Abstract

Recent works in self-supervised learning have advanced the state-of-the-art by relying on the *contrastive learning* paradigm, which learns representations by pushing positive pairs, or similar examples from the same class, closer together while keeping negative pairs far apart. Despite the empirical successes, theoretical foundations are limited – prior analyses assume conditional independence of the positive pairs given the same class label, but recent empirical applications use heavily correlated positive pairs (i.e., data augmentations of the same image). Our work analyzes contrastive learning without assuming conditional independence of positive pairs using a novel concept of the *augmentation graph* on data. Edges in this graph connect augmentations of the same datapoint, and ground-truth classes naturally form connected sub-graphs. We propose a loss that performs spectral decomposition on the population augmentation graph and can be succinctly written as a contrastive learning objective on neural net representations. Minimizing this objective leads to features with provable accuracy guarantees under linear probe evaluation. By standard generalization bounds, these accuracy guarantees also hold when minimizing the training contrastive loss. Empirically, the features learned by our objective can match or outperform several strong baselines on benchmark vision datasets. In all, this work provides the first provable analysis for contrastive learning where guarantees for linear probe evaluation can apply to realistic empirical settings.

1 Introduction

Recent empirical breakthroughs have demonstrated the effectiveness of self-supervised learning, which trains representations on unlabeled data with surrogate losses and self-defined supervision signals (Bachman et al., 2019, Bardes et al., 2021, Caron et al., 2020, Chen and He, 2020, Henaff, 2020, Hjelm et al., 2018, Misra and Maaten, 2020, Oord et al., 2018, Tian et al., 2019, 2020a, Wu et al., 2018, Ye et al., 2019, Zbontar et al., 2021). Self-supervision signals in computer vision are often defined by using data augmentation to produce multiple views of the same image. For example, the recent contrastive learning objectives (Arora et al., 2019, Chen et al., 2020a,b,c, He et al., 2020) encourage closer representations for augmentations (views) of the same natural datapoint than for randomly sampled pairs of data.

Despite the empirical successes, there is a limited theoretical understanding of why self-supervised losses learn representations that can be adapted to downstream tasks, for example,

using linear heads. Recent mathematical analyses for contrastive learning by Arora et al. (2019), Tosh et al. (2020, 2021) provide guarantees under the assumption that two views are somewhat conditionally independent given the label or a hidden variable. However, in practical algorithms for computer vision applications, the two views are augmentations of a natural image and usually exhibit a strong correlation that is difficult to be de-correlated by conditioning. They are not independent conditioned on the label, and we are only aware that they are conditionally independent given the natural image, which is too complex to serve as a hidden variable with which prior works can be meaningfully applied. Thus the existing theory does not appear to explain the practical success of self-supervised learning.

This paper presents a theoretical framework for self-supervised learning without requiring conditional independence. We design a principled, practical loss function for learning neural net representations that resembles state-of-the-art contrastive learning methods. We prove that, under a simple and realistic data assumption, linear classification using representations learned on a polynomial number of unlabeled data samples can recover the ground-truth labels of the data with high accuracy.

The fundamental data property that we leverage is a notion of continuity of the population data within the same class. Though a random pair of examples from the same class can be far apart, the pair is often connected by (many) sequences of examples, where consecutive examples in the sequences are close neighbors within the same class. This property is more salient when the neighborhood of an example includes many different types of augmentations. Prior work (Wei et al., 2020) empirically demonstrates this type of connectivity property and uses it in the analysis of pseudolabeling algorithms.

More formally, we define the *population augmentation graph*, whose vertices are all the augmented data in the *population* distribution, which can be an exponentially large or infinite set. Two vertices are connected with an edge if they are augmentations of the same natural example. Our main assumption is that for some proper $m \in \mathbb{Z}^+$, the sparsest m-partition (Definition 3.4) is large. This intuitively states that we can't split the augmentation graph into too many disconnected subgraphs by only removing a sparse set of edges. This assumption can be seen as a graph-theoretic version of the continuity assumption on population data. We also assume that there are very few edges across different ground-truth classes (Assumption 3.5). Figure 1 (left) illustrates a realistic scenario where dog and cat are the ground-truth categories, between which edges are very rare. Each breed forms a sub-graph that has sufficient inner connectivity and thus cannot be further partitioned.

Our assumption fundamentally does not require conditional independence and can allow disconnected sub-graphs within a class. The classes in the downstream task can be also somewhat flexible as long as they are disconnected in the augmentation graph. For example, when the augmentation graph consists of m disconnected sub-graphs corresponding to fine-grained classes, our assumptions allow the downstream task to have any $r \le m$ coarse-grained classes containing these fine-grained classes as a sub-partition. Prior work (Wei et al., 2020) on pseudolabeling algorithms essentially requires an exact alignment between sub-graphs and downstream classes (i.e., r = m). They face this limitation because their analysis requires fitting discrete pseudolabels on the unlabeled data. We avoid this difficulty because we consider directly learning continuous representations on the unlabeled data.

We apply spectral decomposition—a classical approach for graph partitioning, also known as spectral clustering (Ng et al., 2001, Shi and Malik, 2000) in machine learning—to the adjacency matrix defined on the population augmentation graph. We form a matrix where the top-k eigenvectors

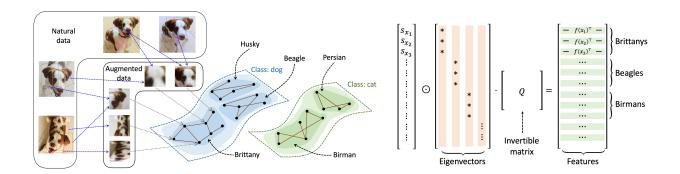

Figure 1: Left: demonstration of the population augmentation graph. Two augmented data are connected if they are views of the same natural datapoint. Augmentations of data from different classes in the downstream tasks are assumed to be nearly disconnected, whereas there are more connections within the same class. We allow the existence of disconnected sub-graphs within a class corresponding to potential sub-classes. Right: decomposition of the learned representations. The representations (rows in the RHS) learned by minimizing the population spectral contrastive loss can be decomposed as the LHS. The scalar s_{x_i} is positive for every augmented datapoint x_i . Columns of the matrix labeled "eigenvectors" are the top eigenvectors of the normalized adjacency matrix of the augmentation graph defined in Section 3.1. The operator \odot multiplies row-wise each s_{x_i} with the x_i -th row of the eigenvector matrix. When classes (or sub-classes) are exactly disconnected in the augmentation graph, the eigenvectors are sparse and align with the sub-class structure. The invertible Q matrix does not affect the performance of the rows under the linear probe.

are the columns and interpret each row of the matrix as the representation (in \mathbb{R}^k) of an example. Somewhat surprisingly, we show that this feature extractor can be also recovered (up to some linear transformation) by minimizing the following population objective which is similar to the standard contrastive loss (Section 3.2):

$$\mathcal{L}(f) = -2 \cdot \mathbb{E}_{x,x^+} \left[f(x)^\top f(x^+) \right] + \mathbb{E}_{x,x^-} \left[\left(f(x)^\top f(x^-) \right)^2 \right],$$

where (x, x^+) is a pair of augmentations of the same datapoint, (x, x^-) is a pair of independently random augmented data, and f is a parameterized function from augmented data to \mathbb{R}^k . Figure 1 (right) illustrates the relationship between the eigenvector matrix and the learned representations. We call this loss the *population spectral contrastive loss*.

We analyze the linear classification performance of the representations learned by minimizing the population spectral contrastive loss. Our main result (Theorem 3.7) shows that when the representation dimension exceeds the maximum number of disconnected sub-graphs, linear classification with learned representations is guaranteed to have a small error. Our theorem reveals a trend that a larger representation dimension is needed when there are a larger number of disconnected sub-graphs. Our analysis relies on novel techniques tailored to linear probe performance, which have not been studied in the spectral graph theory community to the best of our knowledge.

The spectral contrastive loss also works on empirical data. Since our approach optimizes parametric loss functions, guarantees involving the population loss can be converted to finite sample results using off-the-shelf generalization bounds. The sample complexity is polynomial in the

Rademacher complexity of the model family and other relevant parameters (Theorem 4.1 and Theorem 4.2).

In summary, our main theoretical contributions are: 1) we propose a simple contrastive loss motivated by spectral decomposition of the population data graph, 2) under simple and realistic assumptions, we provide downstream classification guarantees for the representation learned by minimizing this loss on population data, and 3) our analysis is easily applicable to deep networks with polynomial unlabeled samples via off-the-shelf generalization bounds.

In addition, we implement and test the proposed spectral contrastive loss on standard vision benchmark datasets. Our algorithm is simple and doesn't rely on tricks such as stop-gradient which is essential to SimSiam (Chen and He, 2020). We demonstrate that the features learned by our algorithm can match or outperform several strong baselines (Chen et al., 2020a, Chen and He, 2020, Chen et al., 2020c, Grill et al., 2020) when evaluated using a linear probe.

2 Additional related works

Empirical works on self-supervised learning. Self-supervised learning algorithms have been shown to successfully learn representations that benefit downstream tasks (Bachman et al., 2019, Bardes et al., 2021, Caron et al., 2020, Chen et al., 2020a,b,c, He et al., 2020, Henaff, 2020, Hjelm et al., 2018, Misra and Maaten, 2020, Oord et al., 2018, Tian et al., 2019, 2020a, Wu et al., 2018, Xie et al., 2019, Ye et al., 2019, Zbontar et al., 2021). Many recent self-supervised learning algorithms learn features with siamese networks (Bromley et al., 1993), where two neural networks of shared weights are applied to pairs of augmented data. Introducing asymmetry to siamese networks either with a momentum encoder like BYOL (Grill et al., 2020) or by stopping gradient propagation for one branch of the siamese network like SimSiam (Chen and He, 2020) has been shown to effectively avoid collapsing. Contrastive methods (Chen et al., 2020a,c, He et al., 2020) minimize the InfoNCE loss (Oord et al., 2018), where two views of the same data are attracted while views from different data are repulsed.

Theoretical works on self-supervised learning. As briefly discussed in the introduction, several theoretical works have studied self-supervised learning. Arora et al. (2019) provide guarantees for representations learned by contrastive learning on downstream linear classification tasks under the assumption that the positive pairs are conditionally independent given the class label. Theorem 3.3 and Theorem 3.7 of the work of Lee et al. (2020) show that, under conditional independence given the label and/or additional latent variables, representations learned by reconstruction-based self-supervised learning algorithms can achieve small errors in the downstream linear classification task. Lee et al. (2020, Theorem 4.1) generalizes it to approximate conditional independence for Gaussian data and Theorem 4.5 further weakens the assumptions significantly. Tosh et al. (2020) show that contrastive learning representations can linearly recover any continuous functions of the underlying topic posterior under a topic modeling assumption (which also requires conditional independence of the positive pair given the hidden variable). More recently, Theorem 11 of the work of Tosh et al. (2021) provide novel guarantees for contrastive learning under the assumption that there exists a hidden variable h such that the positive pair (x, x^+) are conditionally independent given h and the random variable $p(x|h)p(x^+|h)/p(x)p(x^+)$ has a small variance. However, in practical algorithms for computer vision applications, the two views are two augmentations and thus they are highly correlated. They might be only independent when conditioned on very complex hidden variables such as the original natural image, which might be too complex for the previous results to be meaningfully applied.

We can also compare the assumptions and results on a concrete generative model for the data, our Example 3.8 in Section 3.4, where the data are generated by a mixture of Gaussian or a mixture of manifolds, the label is the index of the mixture, and the augmentations are small Gaussian blurring (i.e., adding Gaussian noise). In this case, the positive pairs (x, x^+) are two points that are very close to each other. To the best of our knowledge, applying Theorem 11 of Tosh et al. (2021) to this case with $h = \bar{x}$ (the natural datapoint) would result in requiring a large (if not infinite) representation dimension. Because x^+ and x are very close, the reconstruction-based algorithms in Lee et al. (2020), when used to predict x^+ from x, will not be able to produce good representations as well.¹

On a technical level, to relate prior works' assumptions to ours, we can consider an almost equivalent version of our assumption (although our proofs do not directly rely on or relate to the discussion below). Let (x, x^+) be a positive pair and let $p(\cdot|x)$ be the conditional distribution of x^+ given x. Starting from x_0 , let us consider a hypothetical Markov chain x_0, \ldots, x_T, \cdots where x_t is drawn from $p(\cdot|x_{t-1})$. Our assumption essentially means that this hypothetical Markov chain of sampling neighbors will mix within the same class earlier than it mixes across the entire population (which might not be possible or takes exponential time). More concretely, the assumption that $\rho_{\lfloor k/2 \rfloor}$ is large compared to α in Theorem 3.7 is roughly equivalent to the existence of a (potentially large) T such that x_0 and x_T are still likely to have the same label, but are sufficiently independent conditioned on this label or some hidden variable. Roughly speaking, prior works (Arora et al., 2019, Tosh et al., 2020, 2021) assume probabilistic structure about x_0 and x_1 (instead of x_0 and x_T), e.g., Arora et al. (2019) and Theorem 11 of Tosh et al. (2021) assume that x_0 and x_1 are independent conditioned on the label and/or a hidden variable. Similar Markov chains on augmentated data have also been used in previous work (Dao et al., 2019) to study properties of data augmentation.

Several other works (Bansal et al., 2020, Tian et al., 2020b, Tsai et al., 2020, Wang and Isola, 2020) also theoretically study self-supervised learning. The work Tsai et al. (2020) prove that self-supervised learning methods can extract task-relevant information and discard task-irrelevant information, but lacks guarantees for solving downstream tasks efficiently with simple (e.g., linear) models. Tian et al. (2020b) study why non-contrastive self-supervised learning methods can avoid feature collapse. Zimmermann et al. (2021) prove that for a specific data generating process, contrastvie learning can learn representations that recover the latent variable. Cai et al. (2021) analyze domain adaptation algorithms for subpopulation shift with a similar expansion condition as (Wei et al., 2020) while also allowing disconnected parts within each class, but require access to ground-truth labels during training. In contrast, our algorithm doesn't need labels during pre-training.

Co-training and multi-view learning are related settings which leverage two distinct "views" (i.e., feature subsets) of the data (Balcan et al., 2005, Blum and Mitchell, 1998, Dasgupta et al., 2002). The original co-training algorithms (Blum and Mitchell, 1998, Dasgupta et al., 2002) assume that the two views are independent conditioned on the true label and leverage this independence to obtain accurate pseudolabels for the unlabeled data. Balcan et al. (2005) relax the requirement on independent views of co-training, by using an "expansion" assumption, which is closely related to our assumption that $\rho_{\lfloor k/2 \rfloor}$ is not too small in Theorem 3.7. Besides recent works (e.g., the work of Tosh et al. (2021)), most co-training or multi-view learning algorithms are quite different from the modern contrastive learning algorithms which use neural network parameterization for vision applications.

Our analysis relies on the normalized adjacency matrix (see Section 3.1), which is closely related to the graph Laplacian regularization that has been studied in the setting of semi-supervised

 $^{^1}$ On a technical level, Example 3.8 does not satisfy the requirement regarding the β quantity in Assumption 4.1 of Lee et al. (2020), if (X_1, X_2) in that paper is equal to (x, x+) here—it requires the label to be correlated with the raw input x, which is not necessarily true in Example 3.8. This can likely be addressed by using a different X_2 .

learning (Nadler et al., 2009, Zhu et al., 2003). In their works, the Laplacian matrix is used to define a regularization term that smooths the predictions on unlabeled data. This regularizer is further added to the supervised loss on labeled data during training. In contrast, we use the normalized adjacency matrix to define the unsupervised training objective in this paper.

3 Spectral contrastive learning on population data

In this section, we introduce our theoretical framework, the spectral contrastive loss, and the main analysis of the performance of the representations learned on population data.

We use $\overline{\mathcal{X}}$ to denote the set of all natural data (raw inputs without augmentation). We assume that each $\overline{x} \in \overline{\mathcal{X}}$ belongs to one of r classes, and let $y: \overline{\mathcal{X}} \to [r]$ denote the ground-truth (deterministic) labeling function. Let $\mathcal{P}_{\overline{\mathcal{X}}}$ be the population distribution over $\overline{\mathcal{X}}$ from which we draw training data and test our final performance. In the main body of the paper, for the ease of exposition, we assume $\overline{\mathcal{X}}$ to be a finite but exponentially large set (e.g., all real vectors in \mathbb{R}^d with bounded precision). This allows us to use sums instead of integrals and avoid non-essential nuances/jargons related to functional analysis. See Section F for the straightforward extensions to the case where $\overline{\mathcal{X}}$ is an infinite compact set (with mild regularity conditions).²

We next formulate data augmentations. Given a natural data sample $\bar{x} \in \overline{\mathcal{X}}$, we use $\mathcal{A}(\cdot|\bar{x})$ to denote the distribution of its augmentations. For instance, when \bar{x} represents an image, $\mathcal{A}(\cdot|\bar{x})$ can be the distribution of common augmentations (Chen et al., 2020a) that includes Gaussian blur, color distortion and random cropping. We use \mathcal{X} to denote the set of all augmented data, which is the union of supports of all $\mathcal{A}(\cdot|\bar{x})$ for $\bar{x} \in \overline{\mathcal{X}}$. As with $\overline{\mathcal{X}}$, we also assume that \mathcal{X} is a finite but exponentially large set, and denote $N = |\mathcal{X}|$. None of the bounds will depend on N — it is only defined and assumed to be finite for the ease of exposition.

We will learn an embedding function $f: \mathcal{X} \to \mathbb{R}^k$, and then evaluate its quality by the minimum error achieved with a linear probe. Concretely, a linear classifier has weights $B \in \mathbb{R}^{k \times r}$ and predicts $g_{f,B}(x) = \arg\max_{i \in [r]} (f(x)^\top B)_i$ for an augmented datapoint x ($\arg\max$ breaks tie arbitrarily). Then, given a natural data sample \bar{x} , we ensemble the predictions on augmented data and predict:

$$\bar{g}_{f,B}(\bar{x}) := \underset{i \in [r]}{\operatorname{arg max}} \Pr_{x \sim \mathcal{A}(\cdot | \bar{x})} \left[g_{f,B}(x) = i \right].$$

Define the *linear probe* error as the error of the best possible linear classifier on the representations:

$$\mathcal{E}(f) := \min_{B \in \mathbb{R}^{k \times r}} \Pr_{\bar{x} \sim \mathcal{P}_{\overline{x}}} [y(\bar{x}) \neq \bar{g}_{f,B}(\bar{x})] \tag{1}$$

3.1 Augmentation graph and spectral decomposition

Our approach is based on the central concept of **population augmentation graph**, denoted by $G(\mathcal{X}, w)$, where the vertex set is all augmentation data \mathcal{X} and w denotes the edge weights defined below. For any two augmented data $x, x' \in \mathcal{X}$, define the weight $w_{xx'}$ as the marginal probability of generating the pair x and x' from a random natural data $\bar{x} \sim \mathcal{P}_{\overline{\mathcal{X}}}$:

$$w_{xx'} := \mathbb{E}_{\bar{x} \sim \mathcal{P}_{\overline{x}}} \left[\mathcal{A}(x|\bar{x}) \mathcal{A}(x'|\bar{x}) \right]$$
 (2)

Therefore, the weights sum to 1 because the total probability mass is 1: $\sum_{x,x'\in\mathcal{X}} w_{xx'} = 1$. The relative magnitude intuitively captures the closeness between x and x' with respect to the augmentation transformation. For most of the unrelated x and x', the value $w_{xx'}$ will be significantly

²In Section F, we will deal with an infinite graph, its adjacency operator (instead of adjacency matrix), and the eigenfunctions of the adjacency operator (instead of eigenvectors) essentially in the same way.

smaller than the average value. For example, when x and x' are random croppings of a cat and a dog respectively, $w_{xx'}$ will be essentially zero because no natural data can be augmented into both x and x'. On the other hand, when x and x' are very close in ℓ_2 -distance or very close in ℓ_2 -distance up to color distortion, $w_{xx'}$ is nonzero because they may be augmentations of the same image with Gaussian blur and color distortion. We say that x and x' are connected with an edge if $w_{xx'} > 0$. See Figure 1 (left) for more illustrations.

Given the structure of the population augmentation graph, we apply spectral decomposition to the population graph to construct principled embeddings. The eigenvalue problems are closely related to graph partitioning as shown in spectral graph theory (Chung and Graham, 1997) for both worst-case graphs (Cheeger, 1969, Kannan et al., 2004, Lee et al., 2014, Louis et al., 2011) and random graphs (Abbe, 2017, Lei et al., 2015, McSherry, 2001). In machine learning, spectral clustering (Ng et al., 2001, Shi and Malik, 2000) is a classical algorithm that learns embeddings by eigendecomposition on an empirical distance graph and invoking k-means on the embeddings.

We will apply eigendecomposition to the *population* augmentation graph (and then later use linear probe for classification). Let $w_x = \sum_{x' \in \mathcal{X}} w_{xx'}$ be the total weights associated to x, which is often viewed as an analog of the degree of x in weighted graph. A central object in spectral graph theory is the so-called *normalized adjacency matrix*:

$$\overline{A} := D^{-1/2} A D^{-1/2}$$
 (3)

where $A \in \mathbb{R}^{N \times N}$ is adjacency matrix with entires $A_{xx'} = w_{xx'}$ and $D \in \mathbb{R}^{N \times N}$ is a diagonal matrix with $D_{xx} = w_x$.

Standard spectral graph theory approaches produce vertex embeddings as follows. Let $\gamma_1, \gamma_2, \cdots, \gamma_k$ be the k largest eigenvalues of \overline{A} , and v_1, v_2, \cdots, v_k be the corresponding unit-norm eigenvectors. Let $F^* = [v_1, v_2, \cdots, v_k] \in \mathbb{R}^{N \times k}$ be the matrix that collects these eigenvectors in columns, and we refer to it as the eigenvector matrix. Let $u_x^* \in \mathbb{R}^k$ be the x-th row of the matrix F^* . It turns out that u_x^* 's can serve as desirable embeddings of x's because they exhibit clustering structure in Euclidean space that resembles the clustering structure of the graph $G(\mathcal{X}, w)$.

3.2 From spectral decomposition to spectral contrastive learning

The embeddings u_x^* obtained by eigendecomposition are nonparametric—a k-dimensional parameter is needed for every x—and therefore cannot be learned with a realistic amount of data. The embedding matrix F^* cannot be even stored efficiently. Therefore, we will instead parameterize the rows of the eigenvector matrix F^* as a neural net function, and assume embeddings u_x^* can be represented by f(x) for some $f \in \mathcal{F}$, where \mathcal{F} is the hypothesis class containing neural networks. As we'll show in Section 4, this allows us to leverage the extrapolation power of neural networks and learn the representation on a finite dataset.

Next, we design a proper loss function for the feature extractor f, such that minimizing this loss could recover F^* up to some linear transformation. As we will show in Section 4, the resulting population loss function on f also admits an unbiased estimator with finite training samples. Let F be an embedding matrix with u_x on the x-th row, we will first design a loss function of F that can be decomposed into parts about individual rows of F.

We employ the following matrix factorization based formulation for eigenvectors. Consider the objective

$$\min_{F \in \mathbb{R}^{N \times k}} \mathcal{L}_{\mathrm{mf}}(F) := \left\| \overline{A} - FF^{\top} \right\|_{F}^{2}. \tag{4}$$

³We index the matrix A, D by $(x, x') \in \mathcal{X} \times \mathcal{X}$. Generally we index N-dimensional axis by $x \in \mathcal{X}$.

By the classical theory on low-rank approximation (Eckart–Young–Mirsky theorem (Eckart and Young, 1936)), any minimizer \widehat{F} of $\mathcal{L}_{\mathrm{mf}}(F)$ contains scaling of the largest eigenvectors of \overline{A} up to a right transformation—for some orthonormal matrix $R \in \mathbb{R}^{k \times k}$, we have $\widehat{F} = F^* \cdot \mathrm{diag}([\sqrt{\gamma_1}, \ldots, \sqrt{\gamma_k}])R$. Fortunately, multiplying the embedding matrix by any matrix on the right and any diagonal matrix on the left does not change its linear probe performance, which is formalized by the following lemma.

Lemma 3.1. Consider an embedding matrix $F \in \mathbb{R}^{N \times k}$ and a linear classifier $B \in \mathbb{R}^{k \times r}$. Let $D \in \mathbb{R}^{N \times N}$ be a diagonal matrix with positive diagonal entries and $Q \in \mathbb{R}^{k \times k}$ be an invertible matrix. Then, for any embedding matrix $\widetilde{F} = D \cdot F \cdot Q$, the linear classifier $\widetilde{B} = Q^{-1}B$ on \widetilde{F} has the same prediction as B on F. As a consequence, we have

$$\mathcal{E}(F) = \mathcal{E}(\widetilde{F}). \tag{5}$$

where $\mathcal{E}(F)$ denotes the linear probe performance when the rows of F are used as embeddings.

Proof of Lemma 3.1. Let $D=\operatorname{diag}(s)$ where $s_x>0$ for $x\in\mathcal{X}$. Let $u_x,\tilde{u}_x\in\mathbb{R}^k$ be the x-th row of matrices F and \widetilde{F} , respectively. Recall that $g_{u,B}(x)=\arg\max_{i\in[r]}(u_x^\top B)_i$ is the prediction on an augmented datapoint $x\in\overline{\mathcal{X}}$ with representation u_x and linear classifier B. Let $\widetilde{B}=Q^{-1}B$, it's easy to see that $g_{\widetilde{u},\widetilde{B}}(x)=\arg\max_{i\in[r]}(s_x\cdot u_x^\top B)_i$. Notice that $s_x>0$ doesn't change the prediction since it changes all dimensions of $u_x^\top B$ by the same scale, we have $g_{\widetilde{u},\widetilde{B}}(x)=g_{u,B}(x)$ for any augmented datapoint $x\in\mathcal{X}$. The equivalence of loss naturally follows.

The main benefit of objective $\mathcal{L}_{\mathrm{mf}}(F)$ is that it's based on the rows of F. Recall that vectors u_x are the rows of F. Each entry of FF^{\top} is of the form $u_x^{\top}u_{x'}$, and thus $\mathcal{L}_{\mathrm{mf}}(F)$ can be decomposed into a sum of N^2 terms involving terms $u_x^{\top}u_{x'}$. Interestingly, if we reparameterize each row u_x by $w_x^{1/2}f(x)$, we obtain a very similar loss function for f that resembles the contrastive learning loss used in practice (Chen et al., 2020a) as shown below in Lemma 3.2. See Figure 1 (right) for an illustration of the relationship between the eigenvector matrix and the representations learned by minimizing this loss.

We formally define the positive and negative pairs to introduce the loss. Let $\bar{x} \sim \mathcal{P}_{\overline{\mathcal{X}}}$ be a random natural datapoint and draw $x \sim \mathcal{A}(\cdot|\bar{x})$ and $x^+ \sim \mathcal{A}(\cdot|\bar{x})$ independently to form a positive pair (x,x^+) . Draw $\bar{x}' \sim \mathcal{P}_{\overline{\mathcal{X}}}$ and $x^- \sim \mathcal{A}(\cdot|\bar{x}')$ independently with \bar{x},x,x^+ . We call (x,x^-) a negative pair.⁴

Lemma 3.2 (Spectral contrastive loss). Recall that u_x is the x-th row of F. Let $u_x = w_x^{1/2} f(x)$ for some function f. Then, the loss function $\mathcal{L}_{mf}(F)$ is equivalent to the following loss function for f, called spectral contrastive loss, up to an additive constant:

$$\mathcal{L}_{mf}(F) = \mathcal{L}(f) + \text{const}$$
where $\mathcal{L}(f) \triangleq -2 \cdot \mathbb{E}_{x,x^{+}} \left[f(x)^{\top} f(x^{+}) \right] + \mathbb{E}_{x,x^{-}} \left[\left(f(x)^{\top} f(x^{-}) \right)^{2} \right]$ (6)

⁴Though x and x^- are simply two independent draws, we call them negative pairs following the literature (Arora et al., 2019).

Proof of Lemma 3.2. We can expand $\mathcal{L}_{mf}(F)$ and obtain

$$\mathcal{L}_{mf}(F) = \sum_{x,x' \in \mathcal{X}} \left(\frac{w_{xx'}}{\sqrt{w_x w_{x'}}} - u_x^{\top} u_{x'} \right)^2$$

$$= \sum_{x,x' \in \mathcal{X}} \left(\frac{w_{xx'}^2}{w_x w_{x'}} - 2 \cdot w_{xx'} \cdot f(x)^{\top} f(x') + w_x w_{x'} \cdot \left(f(x)^{\top} f(x') \right)^2 \right)$$
(7)

Notice that the first term is a constant that only depends on the graph but not the variable f. By the definition of augmentation graph, $w_{xx'}$ is the probability of a random positive pair being (x, x') while w_x is the probability of a random augmented datapoint being x. We can hence rewrite the sum of last two terms in Equation (7) as Equation (6).

We note that spectral contrastive loss is similar to many popular contrastive losses (Chen et al., 2020a, Oord et al., 2018, Sohn, 2016, Wu et al., 2018). For instance, the contrastive loss in Sim-CLR (Chen et al., 2020a) can be rewritten as (with simple algebraic manipulation)

$$-f(x)^{\top} f(x^+) + \log \left(\exp \left(f(x)^{\top} f(x^+) \right) + \sum_{i=1}^n \exp \left(f(x)^{\top} f(x_i) \right) \right).$$

Here x and x^+ are a positive pair and x_1, \dots, x_n are augmentations of other data. Spectral contrastive loss can be seen as removing $f(x)^{\top}f(x^+)$ from the second term, and replacing the log sum of exponential terms with the average of the squares of $f(x)^{\top}f(x_i)$. We will show in Section 7 that our loss has a similar empirical performance as SimCLR without requiring a large batch size.

3.3 Theoretical guarantees for spectral contrastive loss on population data

In this section, we introduce the main assumptions on the data and state our main theoretical guarantee for spectral contrastive learning on population data.

To formalize the idea that G cannot be partitioned into too many disconnected sub-graphs, we introduce the notions of *Dirichlet conductance* and *sparsest m-partition*, which are standard in spectral graph theory. Dirichlet conductance represents the fraction of edges from S to its complement:

Definition 3.3 (Dirichlet conductance). For a graph $G = (\mathcal{X}, w)$ and a subset $S \subseteq \mathcal{X}$, we define the Dirichlet conductance of S as

$$\phi_G(S) := \frac{\sum_{x \in S, x' \notin S} w_{xx'}}{\sum_{x \in S} w_x}.$$

We note that when S is a singleton, there is $\phi_G(S)=1$ due to the definition of w_x . We introduce the sparsest m-partition to represent the number of edges between m disjoint subsets.

Definition 3.4 (Sparsest m-partition). Let $G = (\mathcal{X}, w)$ be the augmentation graph. For an integer $m \in [2, |\mathcal{X}|]$, we define the sparsest m-partition as

$$\rho_m := \min_{S_1, \dots, S_m} \max \{ \phi_G(S_1), \dots, \phi_G(S_m) \}$$

where S_1, \dots, S_m are non-empty sets that form a partition of \mathcal{X} .

We note that ρ_m increases as m increases 5 . When r is the number of underlying classes, we might expect $\rho_r \approx 0$ since the augmentations from different classes almost compose a disjoint r-

To see this, consider $3 \leq m \leq |\mathcal{X}|$. Let S_1, \dots, S_m be the partition of \mathcal{X} that minimizes the RHS of Definition 3.4. Define set $S'_{m-1} := S_m \cup S_{m-1}$. It is easy to see that $\phi_G(S'_{m-1}) = \frac{\sum_{x \in S'_{m-1}, x' \notin S'_{m-1}} w_{xx'}}{\sum_{x \in S'_{m-1}} w_x} \leq \frac{\sum_{i=m-1}^m \sum_{x \in S_i, x' \notin S_i} w_{xx'}}{\sum_{i=m-1}^m \sum_{x \in S_i} w_x} \leq \frac{\sum_{i=m-1}^m \sum_{x \in S_i} w_{xx'}}{\sum_{i=m-1}^m \sum_{x \in S_i} w_x} \leq \frac{\sum_{i=m-1}^m \sum_{x \in S_i} w_{xx'}}{\sum_{i=m-1}^m \sum_{x \in S_i} w_x} \leq \frac{\sum_{i=m-1}^m \sum_{x \in S_i} w_{xx'}}{\sum_{i=m-1}^m \sum_{x \in S_i} w_x} \leq \frac{\sum_{i=m-1}^m \sum_{x \in S_i} w_{xx'}}{\sum_{i=m-1}^m \sum_{x \in S_i} w_x} \leq \frac{\sum_{i=m-1}^m \sum_{x \in S_i} w_{xx'}}{\sum_{i=m-1}^m \sum_{x \in S_i} w_x} \leq \frac{\sum_{i=m-1}^m \sum_{x \in S_i} w_{xx'}}{\sum_{i=m-1}^m \sum_{x \in S_i} w_x} \leq \frac{\sum_{i=m-1}^m \sum_{x \in S_i} w_{xx'}}{\sum_{i=m-1}^m \sum_{x \in S_i} w_x} \leq \frac{\sum_{i=m-1}^m \sum_{x \in S_i} w_{xx'}}{\sum_{i=m-1}^m \sum_{x \in S_i} w_x} \leq \frac{\sum_{i=m-1}^m \sum_{x \in S_i} w_{xx'}}{\sum_{i=m-1}^m \sum_{x \in S_i} w_x} \leq \frac{\sum_{i=m-1}^m \sum_{x \in S_i} w_{xx'}}{\sum_{i=m-1}^m \sum_{x \in S_i} w_x} \leq \frac{\sum_{i=m-1}^m \sum_{x \in S_i} w_{xx'}}{\sum_{i=m-1}^m \sum_{x \in S_i} w_x} \leq \frac{\sum_{i=m-1}^m \sum_{x \in S_i} w_x}{\sum_{i=m-1}^m \sum_{x \in S_i} w_x} \leq \frac{\sum_{i=m-1}^m \sum_{x \in S_i} w_x}{\sum_{i=m-1}^m \sum_{x \in S_i} w_x} \leq \frac{\sum_{i=m-1}^m \sum_{x \in S_i} w_x}{\sum_{i=m-1}^m \sum_{x \in S_i} w_x} \leq \frac{\sum_{i=m-1}^m \sum_{x \in S_i} w_x}{\sum_{i=m-1}^m \sum_{x \in S_i} w_x} \leq \frac{\sum_{i=m-1}^m \sum_{x \in S_i} w_x}{\sum_{i=m-1}^m \sum_{x \in S_i} w_x} \leq \frac{\sum_{i=m-1}^m \sum_{x \in S_i} w_x}{\sum_{i=m-1}^m \sum_{x \in S_i} w_x} \leq \frac{\sum_{i=m-1}^m \sum_{x \in S_i} w_x}{\sum_{i=m-1}^m \sum_{x \in S_i} w_x}$

way partition of \mathcal{X} . However, for m > r, we can expect ρ_m to be much larger. For instance, in the extreme case when $m = |\mathcal{X}| = N$, every set S_i is a singleton, which implies that $\rho_N = 1$.

Next, we formalize the assumption that very few edges cross different ground-truth classes. It turns out that it suffices to assume that the labels are recoverable from the augmentations (which is also equivalent to that two examples in different classes can rarely be augmented into the same point).

Assumption 3.5 (Labels are recoverable from augmentations). Let $\bar{x} \sim \mathcal{P}_{\overline{\mathcal{X}}}$ and $y(\bar{x})$ be its label. Let the augmentation $x \sim \mathcal{A}(\cdot|\bar{x})$. We assume that there exists a classifier g that can predict $y(\bar{x})$ given x with error at most α . That is, $g(x) = y(\bar{x})$ with probability at least $1 - \alpha$.

We also introduce the following assumption which states that some universal minimizer of the population spectral contrastive loss can be realized by the hypothesis class.

Assumption 3.6 (Realizability). Let \mathcal{F} be a hypothesis class containing functions from \mathcal{X} to \mathbb{R}^k . We assume that at least one of the global minima of $\mathcal{L}(f)$ belongs to \mathcal{F} .

Our main theorem bound from above the linear probe error of the features learned by minimizing the population spectral contrastive loss.

Theorem 3.7. Assume the representation dimension $k \ge 2r$ and Assumption 3.5 holds for $\alpha > 0$. Let \mathcal{F} be a hypothesis class that satisfies Assumption 3.6 and let $f_{pop}^* \in \mathcal{F}$ be a minimizer of $\mathcal{L}(f)$. Then, we have

$$\mathcal{E}(f_{\text{pop}}^*) \leq \widetilde{O}\left(\alpha/\rho_{\lfloor k/2 \rfloor}^2\right).$$

Here we use $\widetilde{O}(\cdot)$ to hide universal constant factors and logarithmic factor in k. We note that $\alpha=0$ when augmentations from different classes are perfectly disconnected in the augmentation graph, in which case the above theorem guarantees the exact recovery of the ground truth. Generally, we expect α to be an extremely small constant independent of k, whereas $\rho_{\lfloor k/2 \rfloor}$ increases with k and can be much larger than α when k is reasonably large. For instance, when there are t sub-graphs that have sufficient inner connections, we expect ρ_{t+1} to be on the order of a constant because any t+1 partition needs to break one sub-graph into two pieces and incur a large conductance. We characterize the ρ_k 's growth on more concrete distributions in the next subsection.

Previous works on graph partitioning (Arora et al., 2009, Lee et al., 2014, Leighton and Rao, 1999) often analyze the so-called rounding algorithms that conduct clustering based on the representations of unlabeled data and do not analyze the performance of linear probe (which has access to labeled data). These results provide guarantees on the approximation ratio—the ratio between the conductance of the obtained partition to the best partition—which may depend on graph size (Arora et al., 2009) that can be exponentially large in our setting. The approximation ratio guarantee does not lead to a guarantee on the representations' performance on downstream tasks. Our guarantees are on the linear probe accuracy on the downstream tasks and independent of the graph size. We rely on the formulation of the downstream task's labeling function (Assumption 3.5) as well as a novel analysis technique that characterizes the linear structure of the representations. In Section B, we provide the proof of Theorem 3.7 as well as its more generalized version where k/2 is relaxed to be any constant fraction of k. A proof sketch of Theorem 3.7 is given in Section 6.

 $[\]max\{\phi_G(S_{m-1}),\phi_G(S_m)\}. \text{ Notice that } S_1,\cdots,S_{m-2},S'_{m-1} \text{ are } m-1 \text{ non-empty sets that form a partition of } \mathcal{X}, \text{ by Definition 3.4 we have } \rho_{m-1} \leq \max\{\phi_G(S_1),\cdots,\phi_G(S_{m-2}),\phi_G(S'_{m-1})\} \leq \max\{\phi_G(S_1),\cdots,\phi_G(S_m)\} = \rho_m.$

3.4 Provable instantiation of Theorem 3.7 to mixture of manifold data

In this section, we exemplify Theorem 3.7 on an example where the natural data distribution is a mixture of manifolds, and the augmentation transformation is adding Gaussian noise.

Example 3.8 (Mixture of manifolds). Suppose $\mathcal{P}_{\overline{\mathcal{X}}}$ is mixture of $r \leq d$ distributions P_1, \dots, P_r , where each P_i is generated by some κ -bi-Lipschitz⁶ generator $Q : \mathbb{R}^{d'} \to \mathbb{R}^d$ on some latent variable $z \in \mathbb{R}^{d'}$ with $d' \leq d$ which as a mixture of Gaussian distribution:

$$x \sim P_i \iff x = Q(z), z \sim \mathcal{N}(\mu_i, \frac{1}{d'} \cdot I_{d' \times d'}).$$

Let the data augmentation of a natural data sample \bar{x} is $\bar{x} + \xi$ where $\xi \sim \mathcal{N}(0, \frac{\sigma^2}{d} \cdot I_{d \times d})$ is isotropic Gaussian noise with $0 < \sigma \lesssim \frac{1}{\sqrt{d}}$. We also assume $\min_{i \neq j} \|\mu_i - \mu_j\|_2 \gtrsim \frac{\kappa \cdot \sqrt{\log d}}{\sqrt{d'}}$.

Let $\bar{y}(x)$ be the most likely mixture index i that generates x: $\bar{y}(x) := \arg\max_i P_i(x)$. The simplest downstream task can have label $y(x) = \bar{y}(x)$. More generally, let $r' \leq r$ be the number of labels, and the label $y(x) \in [r']$ in the downstream task be equal to $\pi(\bar{y}(x))$ where π is a function that maps [r] to [r'].

We note that the intra-class distance in the latent space is on the scale of $\Omega(1)$, which can be much larger than the distance between class means which is assumed to be $\gtrsim \frac{\kappa \cdot \sqrt{\log d}}{\sqrt{d'}}$. Therefore, distance-based clustering algorithms do not apply. Moreover, in the simple downstream tasks, the label for x could be just the index of the mixture where x comes from. We also allow downstream tasks that merge the r components into r' labels as long as each mixture component gets the same label. We apply Theorem 3.7 and get the following theorem:

Theorem 3.9. When $k \geq 2r+2$, Example 3.8 satisfies Assumption 3.5 with $\alpha \leq \frac{1}{\operatorname{poly}(d)}$, and has $\rho_{\lfloor k/2 \rfloor} \gtrsim \frac{\sigma}{\kappa \sqrt{d}}$. As a consequence, the error bound is $\mathcal{E}(f_{\operatorname{pop}}^*) \leq \widetilde{O}\left(\frac{\kappa^2}{\sigma^2 \cdot \operatorname{poly}(d)}\right)$.

The theorem above guarantees small error even when σ is polynomially small. In this case, the augmentation noise has a much smaller scale than the data (which is at least on the order of $1/\kappa$). This suggests that contrastive learning can non-trivially leverage the structure of the underlying data and learn good representations with relatively weak augmentation. To the best of our knowledge, it is difficult to apply the theorems in previous works (Arora et al., 2019, Lee et al., 2020, Tosh et al., 2020, 2021, Wei et al., 2020) to this example and get similar guarantees with polynomial dependencies on d, σ , κ . The work of Wei et al. (2020) can apply to the setting where r is known and the downstream label is equal to $\bar{y}(x)$, but cannot handle the case when r is unknown or when two mixture component can have the same label. We refer the reader to the related work section for more discussions and comparisons. The proof can be found in Section C.

4 Finite-sample generalization bounds

In Section 3, we provide guarantees for spectral contrastive learning on population data. In this section, we show that these guarantees can be naturally extended to the finite-sample regime with standard concentration bounds. In particular, given a training dataset $\{\bar{x}_1, \bar{x}_2, \cdots, \bar{x}_n\}$ with $\bar{x}_i \sim \mathcal{P}_{\overline{\mathcal{X}}}$, we learn a feature extractor by minimizing the following *empirical spectral contrastive loss*:

$$\widehat{\mathcal{L}}_n(f) := -\frac{2}{n} \sum_{i=1}^n \mathbb{E}_{x^+ \sim \mathcal{A}(\cdot \mid \bar{x}_i) \atop x^+ \sim \mathcal{A}(\cdot \mid \bar{x}_i)} \left[f(x)^\top f(x^+) \right] + \frac{1}{n(n-1)} \sum_{i \neq j} \mathbb{E}_{x^- \sim \mathcal{A}(\cdot \mid \bar{x}_i) \atop x^- \sim \mathcal{A}(\cdot \mid \bar{x}_j)} \left[\left(f(x)^\top f(x^-) \right)^2 \right].$$

⁶A κ bi-Lipschitz function satisfies $\frac{1}{\kappa}\left\|f(x)-f(y)\right\|_{2}\leq\left\|x-y\right\|_{2}\leq\kappa\left\|f(x)-f(y)\right\|_{2}$.

It is worth noting that $\widehat{\mathcal{L}}_n(f)$ is an unbiased estimator of the population spectral contrastive loss $\mathcal{L}(f)$. (See Claim D.2 for a proof.) Therefore, we can derive generalization bounds via off-the-shelf concentration inequalities. Let \mathcal{F} be a hypothesis class containing feature extractors from \mathcal{X} to \mathbb{R}^k . We extend Rademacher complexity to function classes with high-dimensional outputs and define the Rademacher complexity of \mathcal{F} on n data as $\widehat{\mathcal{R}}_n(\mathcal{F}) := \max_{x_1, \cdots, x_n \in \mathcal{X}} \mathbb{E}_{\sigma} \left[\sup_{f \in \mathcal{F}, i \in [k]} \frac{1}{n} \left(\sum_{j=1}^n \sigma_j f_i(x_j) \right) \right]$, where σ is a uniform random vector in $\{-1, 1\}^n$ and $f_i(z)$ is the i-th dimension of f(z).

Recall that $f_{pop}^* \in \mathcal{F}$ is a minimizer of $\mathcal{L}(f)$. The following theorem with proofs in Section D.1 bounds the population loss of a feature extractor trained with finite data:

Theorem 4.1. For some $\kappa > 0$, assume $||f(x)||_{\infty} \leq \kappa$ for all $f \in \mathcal{F}$ and $x \in \mathcal{X}$. Let $f_{pop}^* \in \mathcal{F}$ be a minimizer of the population loss $\mathcal{L}(f)$. Given a random dataset of size n, let $\hat{f}_{emp} \in \mathcal{F}$ be a minimizer of empirical loss $\widehat{\mathcal{L}}_n(f)$. Then, when Assumption 3.6 holds, with probability at least $1 - \delta$ over the randomness of data, we have

$$\mathcal{L}(\hat{f}_{emp}) \leq \mathcal{L}(f_{pop}^*) + c_1 \cdot \widehat{\mathcal{R}}_{n/2}(\mathcal{F}) + c_2 \cdot \left(\sqrt{\frac{\log 2/\delta}{n}} + \delta\right),$$

where constants $c_1 \lesssim k^2 \kappa^2 + k \kappa$ and $c_2 \lesssim k \kappa^2 + k^2 \kappa^4$.

We can apply Theorem 4.1 to any hypothesis class \mathcal{F} of interest (e.g., deep neural networks) and plug in off-the-shelf Rademacher complexity bounds. For instance, in Section D.2 we give a corollary of Theorem 4.1 when \mathcal{F} contains deep neural networks with ReLU activation.

The theorem above shows that we can achieve near-optimal population loss by minimizing empirical loss up to some small excess loss. The following theorem characterizes how the error propagates to the linear probe performance mildly under some spectral gap conditions.

Theorem 4.2. Assume representation dimension $k \ge 4r + 2$, Assumption 3.5 holds for $\alpha > 0$ and Assumption 3.6 holds. Recall γ_i be the *i*-th largest eigenvalue of the normalized adjacency matrix. Then, for any $\epsilon < \gamma_k^2$ and $\hat{f}_{emp} \in \mathcal{F}$ such that $\mathcal{L}(\hat{f}_{emp}) < \mathcal{L}(f_{pop}^*) + \epsilon$, we have:

$$\mathcal{E}(\hat{f}_{\text{emp}}) \lesssim \frac{\alpha}{\rho_{\lfloor k/2 \rfloor}^2} \cdot \log k + \frac{k\epsilon}{\Delta_{\gamma}^2},$$

where $\Delta_{\gamma} := \gamma_{\lfloor 3k/4 \rfloor} - \gamma_k$ is the eigenvalue gap between the $\lfloor 3k/4 \rfloor$ -th and the k-th eigenvalue.

This theorem shows that the error on the downstream task only grows linearly with the error ϵ during pretraining. We can relax Assumption 3.6 to approximate realizability in the sense that \mathcal{F} contains some sub-optimal feature extractor under the population spectral loss and pay an additional error term in the linear probe error bound. The proof of Theorem 4.2 can be found in Section D.3.

5 Guarantee for learning linear probe with labeled data

In this section, we provide theoretical guarantees for learning a linear probe with *labeled* data. Theorem 3.7 guarantees the existence of a linear probe that achieves a small downstream classification error. However, a priori it is unclear how large the margin of the linear classifier can be, so it is hard to apply margin theory to provide generalization bounds for 0-1 loss. We could in principle control the margin of the linear head, but using capped quadratic loss turns

out to suffice and mathematically more convenient. We learn a linear head with the following capped quadratic loss: given a tuple $(z,y(\bar{x}))$ where $z\in\mathbb{R}^k$ is a representation of augmented datapoint $x\sim \mathcal{A}(\cdot|\bar{x})$ and $y(\bar{x})\in[r]$ is the label of \bar{x} , for a linear probe $B\in\mathbb{R}^{k\times r}$ we define loss $\ell((z,y(\bar{x})),B):=\sum_{i=1}^r\min\big\{\big(B^\top z-\bar{y}(\bar{x})\big)_i^2\,,1\big\}$, where $\bar{y}(\bar{x})$ is the one-hot embedding of $y(\bar{x})$ as a r-dimensional vector (1 on the $y(\bar{x})$ -th dimension, 0 on other dimensions). This is a standard modification of quadratic loss in statistical learning theory that ensures the boundedness of the loss for the ease of analysis (Mohri et al., 2018).

The following Theorem 5.1 provides a generalization guarantee for the linear classifier that minimizes capped quadratic loss on a labeled dataset. The key challenge of the proof is showing the existence of a small-norm linear head B that gives small population quadratic loss, which is not obvious from Theorem 3.7 where only small 0-1 error is guaranteed. Recall γ_i is the i-th largest eigenvalue of the the normalized adjacency matrix. Given a labeled dataset $\{(\bar{x}_i,y(\bar{x}_i))\}_{i=1}^n$ where $\bar{x}_i \sim \mathcal{P}_{\overline{\mathcal{X}}}$ and $y(\bar{x}_i)$ is its label, we sample $x_i \sim \mathcal{A}(\cdot|\bar{x}_i)$ for $i \in [n]$.

Theorem 5.1. In the setting of Theorem 3.7, assume $\gamma_k \geq C_{\lambda}$ for some $C_{\lambda} > 0$. Learn a linear probe $\widehat{B} \in \arg\min_{\|B\|_F \leq 1/C_{\lambda}} \sum_{i=1}^n \ell((f_{\text{pop}}^*(x_i), y(\bar{x}_i)), B)$ by minimizing the capped quadratic loss subject to a norm constraint. Then, with probability at least $1 - \delta$ over random data, we have

$$\Pr_{\bar{x} \sim \mathcal{P}_{\overline{\mathcal{X}}}} \left(\bar{g}_{f^*_{\mathsf{pop}}, \widehat{B}}(\bar{x}) \neq y(\bar{x}) \right) \lesssim \frac{\alpha}{\rho_{\lfloor k/2 \rfloor}^2} \cdot \log k + \frac{r}{C_{\lambda}} \cdot \sqrt{\frac{k}{n}} + \sqrt{\frac{\log 1/\delta}{n}}.$$

Here the first term is the population error from Theorem 3.7. The last two terms are the generalization gap from standard concentration inequalities for linear classification and are small when the number of labeled data n is polynomial in the feature dimension k. We note that this result reveals a trade-off when choosing the feature dimension k: when n is fixed, a larger k decreases the population contrastive loss while increases the generalization gap for downstream linear classification. The proof of Theorem 5.1 is in Section E.

6 Proof Sketch of Theorem 3.7

In this section, we give a proof sketch of Theorem 3.7 in a simplified binary classification setting where there are only two classes in the downstream task.

Recall that N is the size of \mathcal{X} . Recall that w_x is the total weight associated with an augmented datapoint $x \in \mathcal{X}$, which can also be thought of as the probability mass of x as a randomly sampled augmented datapoint. In the scope of this section, for demonstrating the key idea, we also assume that x has uniform distribution, i.e., $w_x = \frac{1}{N}$ for any $x \in \mathcal{X}$.

Let $g:\mathcal{X}\to\{0,1\}$ be the Bayes optimal classifier for predicting the label given an augmented datapoint. By Assumption 3.5, g has an error at most α (which is assumed to be small). Thus, we can think of it as the "target" classifier that we aim to recover. We will show that g can be approximated by a linear function on top of the learned features. Recall that v_1, v_2, \cdots, v_k are the top-k unit-norm eigenvectors of \overline{A} and the feature u_x^* for x is the x-th row of the eigenvector matrix $F^* = [v_1, v_2, \cdots, v_k] \in \mathbb{R}^{N \times k}$. As discussed in Section 3.2, the spectral contrastive loss was designed to compute a variant of the eigenvector matrix F^* up to row scaling and right rotation. More precisely, letting $F_{\text{pop}}^* \in \mathbb{R}^{N \times k}$ be the matrix whose rows contain all the learned embeddings, Section 3.2 shows that $F_{\text{pop}}^* = D \cdot F^* \cdot R$ for a positive diagonal matrix D and an orthonormal matrix R, and Lemma 3.1 shows that these transformations do not affect the feature quality. Therefore, in the rest of the section, it suffices to show that linear models on top of F^* gives the labels of g. Let $\vec{g} \in \{0,1\}^N$ be the vector that contains the labels of all the data under the optimal g, i.e.,

 $\vec{g}_x = g(x)$. Given a linear head b, note that F^*b gives the prediction (before the threshold function) for all examples. Therefore, it suffices to show the existence of a vector b such that

$$F^*b \approx \vec{q} \tag{8}$$

Let $L \triangleq I - \overline{A}$ be the normalized Laplacian matrix. Then, v_i 's are the k smallest unit-norm eigenvectors of L with eigenvalues $\lambda_i = 1 - \gamma_i$. Elementary derivations can give a well-known, important property of the Laplacian matrix L: the quadratic form $\vec{g}^{\top}L\vec{g}$ captures the amount of edges across the two groups that are defined by the binary vector \vec{g} (Chung and Graham, 1997):

$$\vec{g}^{\top} L \vec{g} = \frac{1}{2} \cdot \sum_{x, x' \in \mathcal{X}} \frac{w_{xx'}}{\sqrt{w_x w_{x'}}} (\vec{g}_x - \vec{g}_{x'})^2$$
(9)

With slight abuse of notation, suppose (x, x^+) is the random variable for a positive pair. Using that w is the density function for the positive pair and the simplification that $w_x = 1/N$, we can rewrite equation (9) as

$$\vec{g}^{\top} L \vec{g} = \frac{N}{2} \cdot \mathbb{E}_{x,x^{+}} [(\vec{g}_{x} - \vec{g}_{x^{+}})^{2}], \tag{10}$$

Note that $\mathbb{E}_{x,x^+}[(\vec{g}_x-\vec{g}_{x^+})^2]$ is the probability that a positive pair have different labels under the Bayes optimal classifier g. Because Assumption 3.5 assumes that the labels can be almost determined by the augmented data, we can show that two augmentations of the same datapoint should rarely produce different labels under the Bayes optimal classifier. We will prove in Lemma B.5 via simple calculation that

$$\vec{g}^{\top} L \vec{g} \le N \alpha \tag{11}$$

(We can sanity-check the special case when $\alpha=0$, that is, the label is determined by the augmentation. In this case, $g(x)=g(x^+)$ for a positive pair (x,x^+) w.p. 1, which implies $\vec{g}^\top L \vec{g} = \frac{N}{2} \cdot \mathbb{E}_{x,x^+}[(\vec{g}_x - \vec{g}_{x^+})^2] = 0$.)

Next, we use equation (11) to link \vec{g} to the eigenvectors of L. Let $\lambda_{k+1} \leq \ldots \lambda_N$ be the rest of eigenvalues with unit-norm eigenvectors v_{k+1}, \ldots, v_N . Let $\Pi \triangleq \sum_{i=1}^k v_i v_i^{\top}$ and $\Pi_{\perp} \triangleq \sum_{i=k+1}^N v_i v_i^{\top}$ be the projection operators onto the subspaces spanned by the first k and the last N-k eigenvectors, respectively. Equation (11) implies that \vec{g} has limited projection to the subspace of Π_{\perp} :

$$N\alpha \ge \vec{g}^{\top} L \vec{g} = (\Pi \vec{g} + \Pi_{\perp} \vec{g})^{\top} L (\Pi \vec{g} + \Pi_{\perp} \vec{g}) \ge (\Pi_{\perp} \vec{g})^{\top} L (\Pi_{\perp} \vec{g}) \ge \lambda_{k+1} \|\Pi_{\perp} \vec{g}\|_{2}^{2}, \tag{12}$$

where the first inequality follows from dropping the $\|(\Pi \vec{g})^{\top} L \Pi \vec{g}\|_2^2$ and using $\Pi_{\perp} L \Pi = 0$, and the second inequality is because that Π_{\perp} only contains eigenvectors with eigenvalue at least λ_{k+1} .

Note that $\Pi \vec{g}$ is in the span of eigenvectors v_1, \ldots, v_k , that is, the column-span of F^* . Therefore, there exists $b \in \mathbb{R}^k$ such that $\Pi \vec{g} = F^*b$. As a consequence,

$$\|\vec{g} - F^*b\|_2^2 = \|\Pi_\perp \vec{g}\|_2^2 \le \frac{N\alpha}{\lambda_{k+1}}$$
(13)

By higher-order Cheeger inequality (see Lemma B.4), we have that $\lambda_{k+1} \gtrsim \rho_{\lceil k/2 \rceil}^2$. Then, we obtain the mean-squared error bound:

$$\frac{1}{N} \|\vec{g} - F^*b\|_2^2 \le \alpha/\rho_{\lceil k/2 \rceil}^2 \tag{14}$$

The steps above demonstrate the gist of the proofs, which are formalized in more generality in Section B.1. We will also need two minor steps to complete the proof of Theorem 3.7. First, we can convert the mean-squared error bound to classification error bound: because F^*b is close to the binary vector \vec{g} in mean-squared error, $\mathbb{1}\left[F^*b>1/2\right]$ is close to \vec{g} in 0-1 error. (See Claim B.9 for the formal argument.) Next, F^*b only gives the prediction of the model given the augmented datapoint. We will show in Section B.2 that averaging the predictions on the augmentations of a data ponit will not increase the classification error.

7 Experiments

We test spectral contrastive learning on benchmark vision datasets. We minimize the empirical spectral contrastive loss with an encoder network f and sample fresh augmentation in each iteration. The pseudo-code for the algorithm and more implementation details can be found in Section A.

Encoder / feature extractor. The encoder f contains three components: a backbone network, a projection MLP and a projection function. The backbone network is a standard ResNet architecture. The projection MLP is a fully connected network with BN applied to each layer, and ReLU activation applied to each except for the last layer. The projection function takes a vector and projects it to a sphere ball with radius $\sqrt{\mu}$, where $\mu>0$ is a hyperparameter that we tune in experiments. We find that using a projection MLP and a projection function improves the performance.

Linear evaluation protocol. Given the pre-trained encoder network, we follow the standard linear evaluation protocol (Chen and He, 2020) and train a supervised linear classifier on frozen representations, which are from the ResNet's global average pooling layer.

Results. We report the accuracy on CIFAR-10/100 (Krizhevsky and Hinton, 2009) and Tiny-ImageNet (Le and Yang, 2015) in Table 1. Our empirical results show that spectral contrastive learning achieves better performance than two popular baseline algorithms SimCLR (Chen et al., 2020a) and SimSiam (Chen and He, 2020). In Table 2 we report results on ImageNet (Deng et al., 2009) dataset, and show that our algorithm achieves similar performance as other state-of-the-art methods. We note that our algorithm is much more principled than previous methods and doesn't rely on large batch sizes (SimCLR (Chen et al., 2020a)), momentum encoders (BYOL (Grill et al., 2020) and MoCo (He et al., 2020)) or additional tricks such as stop-gradient (SimSiam (Chen and He, 2020)).

Datasets	CIFAR-10			CIFAR-100			Tiny-ImageNet		
Epochs	200	400	800	200	400	800	200	400	800
SimCLR (repro.)	83.73	87.72	90.60	54.74	61.05	63.88	43.30	46.46	48.12
SimSiam (repro.)	87.54	90.31	91.40	61.56	64.96	65.87	34.82	39.46	46.76
Ours	88.66	90.17	92.07	62.45	65.82	66.18	41.30	45.36	49.86

Table 1: Top-1 accuracy under linear evaluation protocal.

	SimCLR	BYOL	MoCo v2	SimSiam	Ours
acc. (%)	66.5	66.5	67.4	68.1	66.97

Table 2: ImageNet linear evaluation accuracy with 100-epoch pre-training. All results but ours are reported from (Chen and He, 2020). We use batch size 384 during pre-training.

8 Conclusion

In this paper, we present a novel theoretical framework of self-supervised learning and provide provable guarantees for the learned representations on downstream linear classification. We hope our study can facilitate future theoretical analyses of self-supervised learning and inspire new prac-

tical algorithms. For instance, one interesting future direction is to design better algorithms with more advanced techniques in spectral graph theory.

A Experiment details

The pseudo-code for our empirical algorithm is summarized in Algorithm 1.

Algorithm 1 Spectral Contrastive Learning

```
Require: batch size N, structure of encoder network f

1: for sampled minibatch \{\bar{x}_i\}_{i=1}^N do

2: for i \in \{1, \dots, N\} do

3: draw two augmentations x_i = \operatorname{aug}(\bar{x}_i) and x_i' = \operatorname{aug}(\bar{x}_i).

4: compute z_i = f(x_i) and z_i' = f(x_i').

5: compute loss \mathcal{L} = -\frac{2}{N} \sum_{i=1}^N z_i^\top z_i' + \frac{1}{N(N-1)} \sum_{i \neq j} (z_i^\top z_j')^2

6: update f to minimize \mathcal{L}

7: return encoder network f(\cdot)
```

Our results with different hyperparameters on CIFAR-10/100 and Tiny-ImageNet are listed in Table 3.

Datasets	CIFAR-10			CIFAR-100			Tiny-ImageNet		
Epochs	200	400	800	200	400	800	200	400	800
SimCLR (repro.)	83.73	87.72	90.60	54.74	61.05	63.88	43.30	46.46	48.12
SimSiam (repro.)	87.54	90.31	91.40	61.56	64.96	65.87	34.82	39.46	46.76
Ours ($\mu = 1$)	86.47	89.90	92.07	59.13	63.83	65.52	28.76	33.94	40.82
Ours ($\mu = 3$)	87.72	90.09	91.84	61.05	64.79	66.18	40.06	42.52	49.86
Ours ($\mu = 10$)	88.66	90.17	91.01	62.45	65.82	65.16	41.30	45.36	47.84

Table 3: Top-1 accuracy under linear evaluation protocal.

Additional details about the encoder. For the backbone network, we use the CIFAR variant of ResNet18 for CIFAR-10 and CIFAR-100 experiments and use ResNet50 for Tiny-ImageNet and ImageNet experiments. For the projection MLP, we use a 2-layer MLP with hidden and output dimensions 1000 for CIFAR-10, CIFAR100, and Tiny-ImageNet experiments. We use a 3-layer MLP with hidden and output dimension 8192 for ImageNet experiments. We set $\mu=10$ in the ImageNet experiment, and set $\mu\in\{1,3,10\}$ for the CIFAR-10/100 and Tiny-ImageNet experiments.

Training the encoder. We train the neural network using SGD with momentum 0.9. The learning rate starts at 0.05 and decreases to 0 with a cosine schedule. On CIFAR-10/100 and Tiny-ImageNet we use weight decay 0.0005 and train for 800 epochs with batch size 512. On ImageNet we use weight decay 0.0001 and train for 100 epochs with batch size 384. We use 1 GTX 1080 GPU for CIFAR-10/100 and Tiny-ImageNet experiments, and use 8 GTX 1080 GPUs for ImageNet experiments.

Linear evaluation protocol. We train the linear head using SGD with batch size 256 and weight decay 0 for 100 epochs, learning rate starts at 30.0 and is decayed by 10x at the 60th and 80th epochs.

Image transformation details. We use the same augmentation strategy as described in (Chen and He, 2020).

B Proofs for Section 3

We first prove a more generalized version of Theorem 3.7 in section B.1, and then prove Theorem 3.7 in Section B.2.

B.1 A generalized version of Theorem 3.7

For the proof we will follow the convention in literature (Lee et al., 2014) and define the *nor-malized Laplacian matrix* as follows:

Definition B.1. Let $G = (\mathcal{X}, w)$ be the augmentation graph defined in Section 3.1. The normalized Laplacian matrix of the graph is defined as $L = I - D^{-1/2}AD^{-1/2}$, where A is the adjacency matrix with $A_{xx'} = w_{xx'}$ and D is a diagonal matrix with $D_{xx} = w_x$.

It is easy to see that $L = I - \overline{A}$ where \overline{A} is the normalized adjacency matrix defined in Section 3.1. Therefore, when λ_i is the *i*-th smallest eigenvalue of L, $1 - \lambda_i$ is the *i*-th largest eigenvalue of \overline{A} .

We call a function defined on augmented data $\hat{y}: \mathcal{X} \to [r]$ an *extended labeling function*. Given an extended labeling function, we define the following quantity that describes the difference between extended labels of two augmented data of the same natural datapoint:

$$\phi^{\hat{y}} := \sum_{x \ x' \in \mathcal{X}} w_{xx'} \cdot \mathbb{1} \left[\hat{y}(x) \neq \hat{y}(x') \right]. \tag{15}$$

We also define the following quantity that describes the difference between extended label of an augmentated datapoint and the ground truth label of the corresponding natural datapoint:

$$\Delta(y, \hat{y}) := \Pr_{x \sim \mathcal{P}_{\overline{\mathcal{X}}, \tilde{X}} \sim \mathcal{A}(\cdot | x)} (\hat{y}(\tilde{x}) \neq y(x)).$$
(16)

Recall the spectral contrastive loss defined in Section 3.2 is:

$$\mathcal{L}(f) := \mathbb{E}_{x \sim \mathcal{A}(\cdot|x_1), x^+ \sim \mathcal{A}(\cdot|x_1), x' \sim \mathcal{A}(\cdot|x_2)}^{x_1 \sim \mathcal{P}_{\overline{\mathcal{X}}}, x_2 \sim \mathcal{P}_{\overline{\mathcal{X}}}} \left[-2 \cdot f(x)^\top f(x^+) + \left(f(x)^\top f(x') \right)^2 \right].$$

We first state a more general version of Theorem 3.7 as follows.

Theorem B.2. Assume the set of augmented data \mathcal{X} is finite. Let $f_{\text{pop}}^* \in \arg\min_{f:\mathcal{X} \to \mathbb{R}^k} \mathcal{L}(f)$ be a minimizer of the population spectral contrastive loss $\mathcal{L}(f)$ with $k \in \mathcal{Z}^+$. Let $k' \geq r$ such that $k+1 = (1+\zeta)k'$, where $\zeta \in (0,1)$ and $k' \in \mathcal{Z}^+$. Then, there exists a linear probe $B^* \in \mathbb{R}^{r \times k}$ and a universal constant c such that the linear probe predictor satisfies

$$\mathbb{E}_{\bar{x} \sim \mathcal{P}_{\overline{x}}, x \sim \mathcal{A}(\cdot | \bar{x})} \left[\left\| \vec{y}(\bar{x}) - B^* f_{\mathsf{pop}}^*(x) \right\|_2^2 \right] \leq c \cdot \left(\mathsf{poly}(1/\zeta) \cdot \log(k+1) \cdot \frac{\phi^{\hat{y}}}{\rho_{k'}^2} + \Delta(y, \hat{y}) \right),$$

where $\vec{y}(\bar{x})$ is the one-hot embedding of $y(\bar{x})$ and $\rho_{k'}$ is the sparsest m-partition defined in Definition 3.4. Furthermore, the error of the linear probe predictor can be bounded by

$$\Pr_{\bar{x} \sim \mathcal{P}_{\overline{\mathcal{X}}, x} \sim \mathcal{A}(\cdot | \bar{x})} \left(g_{f_{\text{pop}}^*, B^*}(x) \neq y(\bar{x}) \right) \leq 2c \cdot \left(\text{poly}(1/\zeta) \cdot \log(k+1) \cdot \frac{\phi^{\hat{y}}}{\rho_{k'}^2} + \Delta(y, \hat{y}) \right).$$

Also, if we let λ_i be the *i*-th smallest eigenvalue of the normalized Laplacian matrix of the graph of the augmented data, we can find a matrix B^* satisfying the above equations with norm bound $\|B^*\|_F \le 1/(1-\lambda_k)$.

We provide the proof for Theorem B.2 below.

Let $\lambda_1, \lambda_2, \cdots, \lambda_k, \lambda_{k+1}$ be the k+1 smallest eigenvalues of the Laplacian matrix L. The following theorem gives a theoretical guarantee similar to Theorem B.2 except for that the bound depends on λ_{k+1} :

Theorem B.3. Assume the set of augmented data \mathcal{X} is finite. Let $f_{pop}^* \in \arg\min_{f:\mathcal{X} \to \mathbb{R}^k}$ be a minimizer of the population spectral contrastive loss $\mathcal{L}(f)$ with $k \in \mathcal{Z}^+$. Then, for any labeling function $\hat{y}: \mathcal{X} \to [r]$ there exists a linear probe $B^* \in \mathbb{R}^{r \times k}$ with norm $\|B^*\|_F \leq 1/(1-\lambda_k)$ such that

$$\mathbb{E}_{\bar{x} \sim \mathcal{P}_{\overline{\mathcal{X}}}, x \sim \mathcal{A}(\cdot | \bar{x})} \left[\left\| \vec{y}(\bar{x}) - B^* f_{\mathsf{pop}}^*(x) \right\|_2^2 \right] \leq \frac{\phi^{\hat{y}}}{\lambda_{k+1}} + 4\Delta(y, \hat{y}),$$

where $\vec{y}(\bar{x})$ is the one-hot embedding of $y(\bar{x})$. Furthermore, the error can be bounded by

$$\Pr_{\bar{x} \sim \mathcal{P}_{\overline{\mathcal{X}}, x \sim \mathcal{A}(\cdot | \bar{x})}} \left(g_{f_{\text{pop}}^*, B^*}(x) \neq y(\bar{x}) \right) \leq \frac{2\phi^{\hat{y}}}{\lambda_{k+1}} + 8\Delta(y, \hat{y}).$$

We defer the proof of Theorem B.3 to Section B.3.

To get rid of the dependency on λ_{k+1} , we use following higher-order Cheeger's inequality from (Louis and Makarychev, 2014).

Lemma B.4 (Proposition 1.2 in (Louis and Makarychev, 2014)). Let G = (V, w) be a weight graph with |V| = N. Then, for any $t \in [N]$ and $\zeta > 0$ such that $(1 + \zeta)t \in [N]$, there exists a partition S_1, S_2, \dots, S_t of V with

$$\phi_G(S_i) \lesssim \text{poly}(1/\zeta) \sqrt{\lambda_{(1+\zeta)t} \log t},$$

where $\phi_G(\cdot)$ is the Dirichlet conductance defined in Definition 3.3.

Now we prove Theorem B.2 by combining Theorem B.3 and Lemma B.4.

Proof of Theorem B.2. Let $G=(\mathcal{X},w)$ be the augmentation graph. In Lemma B.4 let $(1+\zeta)t=k+1$ and t=k' we have: there exists partition $S_1,\cdots,S_{k'}\subset\mathcal{X}$ such that $\phi_G(S_i)\lesssim \operatorname{poly}(1/\zeta)\sqrt{\lambda_{k+1}\log{(k+1)}}$ for $\forall i\in[k']$. By Definition 3.4, we have $\rho_{k'}\leq \max_{i\in[k']}\phi_G(S_i)\lesssim \operatorname{poly}(1/\zeta)\sqrt{\lambda_{k+1}\log{(k+1)}}$, which leads to $\frac{1}{\lambda_{k+1}}\lesssim \operatorname{poly}(1/\zeta)\cdot \log(k+1)\cdot \frac{1}{\rho_{k'}^2}$. Plugging this bound to Theorem B.3 finishes the proof.

B.2 Proof of Theorem 3.7

We will use the following lemma which gives a connection between $\phi^{\hat{y}}$, $\Delta(y, \hat{y})$ and Assumption 3.5.

Lemma B.5. Let $G = (\mathcal{X}, w)$ be the augmentation graph, r be the number of underlying classes. Let S_1, S_2, \dots, S_r be the partition induced by the classifier g in Assumption 3.5. Then, there exists an extended labeling function \hat{y} such that

$$\Delta(y, \hat{y}) \le \alpha$$

and

$$\phi^{\hat{y}} = \sum_{x,x' \in \mathcal{X}} w_{xx'} \cdot \mathbb{1} \left[\hat{y}(x) \neq \hat{y}(x') \right] \leq 2\alpha.$$

Proof of Lemma B.5. We define function $\hat{y}: \mathcal{X} \to [r]$ as follows: for an augmented data $x \in \mathcal{X}$, we use function $\hat{y}(x)$ to represent the index of set that x is in, i.e., $x \in S_{\hat{y}(x)}$. By Assumption 3.5 it is easy to see $\Delta(y, \hat{y}) \leq \alpha$. On the other hand, we have

$$\begin{split} \phi^{\hat{y}} &= \sum_{x,x' \in \mathcal{X}} w_{xx'} \mathbb{1} \left[\hat{y}(x) \neq \hat{y}(x') \right] \\ &= \sum_{x,x' \in \mathcal{X}} \mathbb{E}_{\bar{x} \sim \mathcal{P}_{\overline{x}}} \left[\mathcal{A}(x|\bar{x}) \mathcal{A}(x'|\bar{x}) \cdot \mathbb{1} \left[\hat{y}(x) \neq \hat{y}(x') \right] \right] \\ &\leq \sum_{x,x' \in \mathcal{X}} \mathbb{E}_{\bar{x} \sim \mathcal{P}_{\overline{x}}} \left[\mathcal{A}(x|\bar{x}) \mathcal{A}(x'|\bar{x}) \cdot \left(\mathbb{1} \left[\hat{y}(x) \neq y(\bar{x}) \right] + \mathbb{1} \left[\hat{y}(x') \neq y(\bar{x}) \right] \right) \right] \\ &= 2 \cdot \mathbb{E}_{\bar{x} \sim \mathcal{P}_{\overline{x}}} \left[\mathcal{A}(x|\bar{x}) \cdot \mathbb{1} \left[\hat{y}(x) \neq y(\bar{x}) \right] \right] \\ &= 2 \cdot \Pr_{\bar{x} \sim \mathcal{P}_{\overline{y}, x} \sim \mathcal{A}(\cdot|\bar{x})} \left(x \notin S_{y(\bar{x})} \right) = 2\alpha. \end{split}$$

Here the inequality is because when $\hat{y}(x) \neq \hat{y}(x')$, there must be $\hat{y}(x) \neq y(\bar{x})$ or $\hat{y}(x') \neq y(\bar{x})$.

Now we give the proof of Theorem 3.7 using Lemma B.5 and Theorem B.2.

Proof of Theorem 3.7. Let S_1, S_2, \cdots, S_r be the partition of \mathcal{X} induced by the classifier g given in Assumption 3.5. Define function $\hat{y}: \mathcal{X} \to [r]$ as follows: for an augmented datapoint $x \in \mathcal{X}$, we use function $\hat{y}(x)$ to represent the index of set that x is in, i.e., $x \in S_{\hat{y}(x)}$. Let $k' = \lfloor \frac{k}{2} \rfloor$ in Theorem B.2, we have $\Pr_{\bar{x} \sim \mathcal{P}_{\overline{\mathcal{X}}}, x \sim \mathcal{A}(\cdot | \bar{x})} \left(g_{f_{\text{pop}}^*, B^*}(x) \neq y(\bar{x}) \right) \lesssim \log(k) \cdot \frac{\phi^{\hat{y}}}{\rho_{\lfloor k/2 \rfloor}^2} + \Delta(y, \hat{y})$. By Lemma B.5 we have $\phi^{\hat{y}} \leq 2\alpha$ and $\Delta(y, \hat{y}) \leq \alpha$, so we have $\Pr_{\bar{x} \sim \mathcal{P}_{\overline{\mathcal{X}}}, x \sim \mathcal{A}(\cdot | \bar{x})} \left(g_{f_{\text{pop}}^*, B^*}(x) \neq y(\bar{x}) \right) \lesssim \frac{\alpha}{\rho_{\lfloor k/2 \rfloor}^2} \cdot \log(k)$. Notice that by definition of ensembled linear probe predictor, $\bar{g}_{f_{\text{pop}}^*, B^*}(\bar{x}) \neq y(\bar{x})$ happens only if more than half of the augmentations of \bar{x} predicts differently from $y(\bar{x})$, so we have $\Pr_{\bar{x} \sim \mathcal{P}_{\overline{\mathcal{X}}}} \left(\bar{g}_{f_{\text{pop}}^*, B^*}(\bar{x}) \neq y(\bar{x}) \right) \leq 2\Pr_{\bar{x} \sim \mathcal{P}_{\overline{\mathcal{X}}}, x \sim \mathcal{A}(\cdot | \bar{x})} \left(g_{f_{\text{pop}}^*, B^*}(x) \neq y(\bar{x}) \right) \lesssim \frac{\alpha}{\rho_{\lfloor k/2 \rfloor}^2} \cdot \log(k)$.

B.3 Proof of Theorem **B.3**

The proof of Theorem B.3 contains two steps. First, we show that when the feature extractor is composed of the minimal eigenvectors of the normalized Laplacian matrix L, we can achieve good linear probe accuracy. Then we show that minimizing $\mathcal{L}(f)$ gives us a feature extractor equally good as the eigenvectors.

For the first step, we use the following lemma which shows that the smallest eigenvectors of L can approximate any function on \mathcal{X} up to an error proportional to the Rayleigh quotient of the function.

Lemma B.6. Let L be the normalized Laplacian matrix of some graph G. Let $N = |\mathcal{X}|$ be total number of augmented data, v_i be the i-th smallest unit-norm eigenvector of L with eigenvalue λ_i (make them orthogonal in case of repeated eignevalues). Let $R(u) := \frac{u^{\top}Lu}{u^{\top}u}$ be the Rayleigh quotient of a vector $u \in \mathbb{R}^N$. Then, for any $k \in \mathcal{Z}^+$ such that k < N and $\lambda_{k+1} > 0$, there exists a vector $b \in \mathbb{R}^k$ with norm $\|b\|_2 \le \|u\|_2$ such that

$$\left\| u - \sum_{i=1}^{k} b_i v_i \right\|_2^2 \le \frac{R(u)}{\lambda_{k+1}} \|u\|_2^2.$$

Proof of Lemma B.6. We can decompose the vector u in the eigenvector basis as:

$$u = \sum_{i=1}^{N} \zeta_i v_i.$$

We have

$$R(u) = \frac{\sum_{i=1}^{N} \lambda_i \zeta_i^2}{\|u\|_2^2}.$$

Let $b \in \mathbb{R}^k$ be the vector such that $b_i = \zeta_i$. Obviously we have $||b||_2^2 \leq ||u||_2^2$. Noticing that

$$\left\| u - \sum_{i=1}^{k} b_i v_i \right\|_2^2 = \sum_{i=k+1}^{N} \zeta_i^2 \le \frac{R(u)}{\lambda_{k+1}} \left\| u \right\|_2^2,$$

which finishes the proof.

We also need the following claim about the Rayleigh quotient R(u) when u is a vector defined by an extended labeling function \hat{y} .

Claim B.7. In the setting of Lemma B.6, let \hat{y} be an extended labeling function. Fix $i \in [r]$. Define function $u_i^{\hat{y}}(x) := \sqrt{w_x} \cdot \mathbb{1}[\hat{y}(x) = i]$ and $u_i^{\hat{y}}$ is the corresponding vector in \mathbb{R}^N . Also define the following quantity:

$$\phi_i^{\hat{y}} := \frac{\sum_{x,x' \in \mathcal{X}} w_{xx'} \cdot \mathbb{1} \left[\left(\hat{y}(x) = i \wedge \hat{y}(x') \neq i \right) \text{ or } \left(\hat{y}(x) \neq i \wedge \hat{y}(x') = i \right) \right]}{\sum_{x \in \mathcal{X}} w_x \cdot \mathbb{1} \left[\hat{y}(x) = i \right]}.$$

Then, we have

$$R(u_i^{\hat{y}}) = \frac{1}{2}\phi_i^{\hat{y}}.$$

Proof of Claim B.7. Let f be any function $\mathcal{X} \to \mathbb{R}$, define function $u(x) := \sqrt{w_x} \cdot f(x)$. Let $u \in \mathbb{R}^N$ be the vector corresponding to u. Let A be the adjacency matrix with $A_{xx'} = w_{xx'}$ and D be the diagonal matrix with $D_{xx} = w_x$. By definition of Laplacian matrix, we have

$$u^{\top} L u = ||u||_{2}^{2} - u^{\top} D^{-1/2} A D^{-1/2} u$$

$$= \sum_{x \in \mathcal{X}} w_{x} f(x)^{2} - \sum_{x, x' \in \mathcal{X}} w_{xx'} f(x) f(x')$$

$$= \frac{1}{2} \sum_{x, x' \in \mathcal{X}} w_{xx'} \cdot (f(x) - f(x'))^{2}.$$

Therefore we have

$$R(u) = \frac{u^{\top} L u}{u^{\top} u}$$
$$= \frac{1}{2} \cdot \frac{\sum_{x, x' \in \mathcal{X}} w_{xx'} \cdot (f(x) - f(x'))^2}{\sum_{x \in \mathcal{X}} w_x \cdot f(x)^2}.$$

Setting $f(x) = \mathbb{1}[\hat{y}(x) = i]$ finishes the proof.

To see the connection between the feature extractor minimizing the population spectral contrastive loss $\mathcal{L}(f)$ and the feature extractor corresponding to eigenvectors of the Laplacian matrix, we use the following lemma which states that the minimizer of the matrix approximation loss defined in Section 3.2 is equivalent to the minimizer of population spectral contrastive loss up to a data-wise scaling.

Lemma B.8. Let \hat{F}_{mf} be the matrix form of a feature extractor $\hat{f}_{mf}: \mathcal{X} \to \mathbb{R}^k$. Then, \hat{F}_{mf} is a minimizer of $\mathcal{L}_{mf}(F)$ if and only if

$$\hat{f}(x) := \frac{1}{\sqrt{w_x}} \cdot \hat{f}_{\rm mf}(x)$$

is a minimizer of the population spectral contrastive loss $\mathcal{L}(f)$.

Proof of Lemma B.8. Notice that

$$\mathcal{L}_{mf}(F) = \left\| (I - L) - FF^{\top} \right\|_{F}^{2} \\
= \sum_{x, x' \in \mathcal{X}} \left(\frac{w_{xx'}}{\sqrt{w_{x}w_{x'}}} - f(x)^{\top} f(x') \right)^{2} \\
= \sum_{x, x' \in \mathcal{X}} \left(f(x)^{\top} f(x') \right)^{2} - 2 \sum_{x, x' \in \mathcal{X}} \frac{w_{xx'}}{\sqrt{w_{x}w_{x'}}} f(x)^{\top} f(x') + \|I - L\|_{F}^{2}. \tag{17}$$

Recall that the definition of spectral contrastive loss is

$$\mathcal{L}(f) := -2 \cdot \mathbb{E}_{x,x^+} \left[f(x)^{\top} f(x^+) \right] + \mathbb{E}_{x,x^-} \left[\left(f(x)^{\top} f(x^-) \right)^2 \right],$$

where (x, x^+) is a random positive pair, (x, x^-) is a random negative pair. We can rewrite the spectral contrastive loss as

$$\mathcal{L}(f) = -2\sum_{x,x'\in\mathcal{X}} w_{xx'} \cdot f(x)^{\top} f(x') + \sum_{x,x'\in\mathcal{X}} w_x w_{x'} \cdot \left(f(x)^{\top} f(x') \right)^2$$

$$= \sum_{x,x'\in\mathcal{X}} \left(\left(\sqrt{w_x} f(x) \right)^{\top} \left(\sqrt{w_{x'}} f(x') \right) \right)^2 - 2\sum_{x,x'\in\mathcal{X}} \frac{w_{xx'}}{\sqrt{w_x w_{x'}}} \left(\sqrt{w_x} f(x) \right)^{\top} \left(\sqrt{w_{x'}} f(x') \right). \tag{18}$$

Compare Equation (17) and Equation (18), we see their minimizers only differ by a term $\sqrt{w_x}$, which finishes the proof.

Note that the minimizer of matrix approximation loss is exactly the largest eigenvectors of I-L (also the smallest eigenvectors of L) due to Eckart–Young–Mirsky theorem, Lemma B.8 indicates that the minimizer of $\mathcal{L}(f)$ is equivalent to the smallest eigenvectors of L up to data-wise scaling.

The following claim shows the relationship between quadratic loss and prediction error.

Claim B.9. Let $f: \mathcal{X} \to \mathbb{R}^k$ be a feature extractor, $B \in \mathbb{R}^{k \times k}$ be a linear head. Let $g_{f,B}$ be the predictor defined in Section 3. Then, for any $x \in \mathcal{X}$ and label $y \in [k]$, we have

$$\|\vec{y} - Bf(x)\|_{2}^{2} \ge \frac{1}{2} \cdot \mathbb{1} [y \ne g_{f,B}(x)],$$

where \vec{y} is the one-hot embedding of y.

Proof. When $y \neq g_{f,B}(x)$, by the definition of $g_{f,B}$ we know that there exists another $y' \neq y$ such that $(Bf(x))_{y'} \geq (Bf(x))_y$. In this case,

$$\|\vec{y} - Bf(x)\|_{2}^{2} \ge (1 - (Bf(x))_{y})^{2} + (Bf(x))_{y'}^{2}$$
(19)

$$\geq \frac{1}{2} \left(1 - (Bf(x))_y + (Bf(x))_{y'} \right)^2 \tag{20}$$

$$\geq \frac{1}{2},\tag{21}$$

where the first inequality is by omitting all the dimensions in the ℓ_2 norm other than the y-th and y'-th dimensions, the second inequality is by Jensen's inequality, and the third inequality is because $(Bf(x))_{y'} \geq (Bf(x))_y$. This proves the inequality in the claim when $y \neq g_{f,B}(x)$. Finally, we finish the proof by noticing that the inequality in this claim obviously holds when $y = g_{f,B}(x)$.

Now we are ready to prove Theorem B.3 by combining Lemma B.6, Claim B.7, Lemma B.8 and Claim B.9.

Proof of Theorem B.3. Let $F_{\text{sc}} = [v_1, v_2, \cdots, v_k]$ be the matrix that contains the smallest k eigenvectors of L as columns, and $f_{\text{sc}}: \mathcal{X} \to \mathbb{R}^k$ is the corresponding feature extractor. For each $i \in [r]$, we define function $u_i^{\hat{y}}(x) := \sqrt{w_x} \cdot \mathbb{1} \left[\hat{y}(x) = i \right]$ and $u_i^{\hat{y}}$ be the corresponding vector in \mathbb{R}^N . By Lemma B.6, there exists a vector $b_i \in \mathbb{R}^k$ with norm bound $\|b_i\|_2 \leq \left\|u_i^{\hat{y}}\right\|_2$ such that

$$\left\| u_i^{\hat{y}} - F_{\text{sc}} b_i \right\|_2^2 \le \frac{R(u_i^{\hat{y}})}{\lambda_{k+1}} \left\| u_i^{\hat{y}} \right\|_2^2. \tag{22}$$

By Claim B.7, we have

$$R(u_i^{\hat{y}}) = \frac{1}{2}\phi_i^{\hat{y}} = \frac{1}{2} \cdot \frac{\sum_{x,x' \in \mathcal{X}} w_{xx'} \cdot \mathbb{1}\left[(\hat{y}(x) = i \wedge \hat{y}(x') \neq i) \text{ or } (\hat{y}(x) \neq i \wedge \hat{y}(x') = i)\right]}{\sum_{x \in \mathcal{X}} w_x \cdot \mathbb{1}\left[\hat{y}(x) = i\right]}.$$

So we can rewrite Equation (22) as:

$$\left\| u_i^{\hat{y}} - F_{\text{sc}} b_i \right\|_2^2 \le \frac{\phi_i^{\hat{y}}}{2\lambda_{k+1}} \cdot \sum_{x \in \mathcal{X}} w_x \cdot \mathbb{1} \left[\hat{y}(x) = i \right]$$

$$= \frac{1}{2\lambda_{k+1}} \sum_{x, x' \in \mathcal{X}} w_{xx'} \cdot \mathbb{1} \left[(\hat{y}(x) = i \wedge \hat{y}(x') \neq i) \text{ or } (\hat{y}(x) \neq i \wedge \hat{y}(x') = i) \right]. \tag{23}$$

Let matrix $U=[u_1^{\hat{y}},\cdots,u_r^{\hat{y}}]$ contains all $u_i^{\hat{y}}$ as columns, and let $u:\mathcal{X}\to\mathbb{R}^r$ be the corresponding feature extractor. Define matrix $B\in\mathbb{R}^{N\times k}$ such that $B^\top=[b_1,\cdots,b_r]$. Summing Equation (23) over all $i\in[r]$ and by the definition of $\phi^{\hat{y}}$ we have

$$\left\| U - F_{\text{sc}} B^{\top} \right\|_{F}^{2} \le \frac{1}{2\lambda_{k+1}} \sum_{x, x' \in \mathcal{X}} w_{xx'} \cdot \mathbb{1} \left[\hat{y}(x) \neq \hat{y}(x') \right] = \frac{\phi^{\hat{y}}}{2\lambda_{k+1}}, \tag{24}$$

where

$$||B||_F^2 = \sum_{i=1}^r ||b_i||_2^2 \le \sum_{i=1}^r ||u_i^{\hat{y}}||_2^2 = \sum_{x \in \mathcal{X}} w_x = 1.$$

Now we come back to the feature extractor f^*_{pop} that minimizes the spectral contrastive loss function $\mathcal{L}(f)$. By Lemma B.8, function $f^*_{mf}(x) := \sqrt{w_x} \cdot f^*_{pop}(x)$ is a minimizer of matrix approximation loss. Let F^*_{mf} be the corresponding matrix. By Eckard-Young-Mirsky theorem, we have

$$F_{\rm mf}^* = F_{\rm sc} D_{\lambda} Q,$$

where Q is an orthonormal matrix and

$$D_{\lambda} = \begin{bmatrix} \sqrt{1 - \lambda_1} & & & \\ & \sqrt{1 - \lambda_2} & & \\ & & \cdots & \\ & & \sqrt{1 - \lambda_k} \end{bmatrix}.$$

Let

$$B^* = BD_{\lambda}^{-1}Q^{-1},$$

and let $\vec{y}(\bar{x})$ be the one-hot embedding of $\hat{y}(\bar{x})$, $\hat{y}(x)$ be the one-hot embedding of $\hat{y}(x)$, we have

$$\begin{split} &\mathbb{E}_{\bar{x}\sim\mathcal{P}_{\overline{x}},x\sim\mathcal{A}(\cdot|\bar{x})}\left[\left\|\vec{y}(\bar{x})-B^*f_{\mathsf{pop}}^*(x)\right\|_2^2\right] \\ \leq &2\mathbb{E}_{\bar{x}\sim\mathcal{P}_{\overline{x}},x\sim\mathcal{A}(\cdot|\bar{x})}\left[\left\|\vec{y}(x)-B^*f_{\mathsf{pop}}^*(x)\right\|_2^2\right] + 2\mathbb{E}_{\bar{x}\sim\mathcal{P}_{\overline{x}},x\sim\mathcal{A}(\cdot|\bar{x})}\left[\left\|\vec{y}(x)-\vec{y}(\bar{x})\right\|_2^2\right] \\ = &2\sum_{x\in\mathcal{X}}w_x\cdot\left\|\vec{y}(x)-B^*f_{\mathsf{pop}}^*(x)\right\|_2^2 + 4\Delta(y,\hat{y}) & \text{(because } w_x \text{ is the probability of } x) \\ = &2\sum_{x\in\mathcal{X}}\|u(x)-B^*f_{\mathsf{mf}}^*(x)\|_2^2 + 4\Delta(y,\hat{y}) & \text{(because } f_{\mathsf{mf}}^*(x) = \sqrt{w_x}\cdot f_{\mathsf{pop}}^*(x)) \\ = &2\left\|U-F_{\mathsf{mf}}^*B^{*\top}\right\|_F^2 + 4\Delta(y,\hat{y}) & \text{(rewrite in matrix form)} \\ = &2\left\|U-F_{\mathsf{sc}}B^\top\right\|_F^2 + 4\Delta(y,\hat{y}) & \text{(by definition of } B^*) \\ \leq &\frac{\phi^{\hat{y}}}{\lambda_{k+1}} + 4\Delta(y,\hat{y}). & \text{(by Equation (24))} \end{split}$$

To bound the error rate, we first notice that Claim B.9 tells us that for any $x \in \mathcal{X}$,

$$\|\vec{y}(\bar{x}) - B^* f_{\text{pop}}^*(x)\|_2^2 \ge \frac{1}{2} \cdot \mathbb{1} \left[g_{f_{\text{pop}}^*, B^*}(x) \ne y(\bar{x}) \right]. \tag{25}$$

Now we bound the error rate on X as follows:

$$\Pr_{\bar{x} \sim \mathcal{P}_{\overline{X}}, x \sim \mathcal{A}(\cdot | \bar{x})} \left(g_{f_{\text{pop}}^*, B^*}(x) \neq y(\bar{x}) \right) \\
\leq 2\mathbb{E}_{\bar{x} \sim \mathcal{P}_{\overline{X}}, x \sim \mathcal{A}(\cdot | \bar{x})} \left[\left\| \vec{y}(\bar{x}) - B^* f_{\text{pop}}^*(x) \right\|_2^2 \right] \\
\leq \frac{2\phi^{\hat{y}}}{\lambda_{k+1}} + 8\Delta(y, \hat{y}). \tag{by Equation (25)}$$

Finally we bound the norm of B^* as

$$||B^*||_F^2 = Tr\left(B^*B^{*\top}\right) = Tr\left(BD_{\lambda}^{-2}B^{\top}\right) \le \frac{1}{1-\lambda_k}||B||_F^2 = \frac{1}{1-\lambda_k}.$$

C Proofs for Section 3.4

In this section, we give a proof of Theorem 3.9.

The following lemma shows that the augmented graph for Example 3.8 satisfies Assumption 3.5 with some bounded α .

Lemma C.1. *In the setting of Theorem 3.9, the data distribution satisfies Assumption 3.5 with* $\alpha \leq \frac{1}{\text{poly}(d')}$.

Proof of Lemma C.1. For any $z \sim \mathcal{N}(\mu_i, \frac{1}{d'} \cdot I_{d' \times d'})$ and any $j \neq i$, by the tail bound of gaussian distribution we have

$$\Pr_{z \sim \mathcal{N}(\mu_i, \frac{1}{d'} \cdot I_{d' \times d'})} \left((z - \mu_i)^\top \left(\frac{\mu_j - \mu_i}{\|\mu_j - \mu_i\|_2} \right) \lesssim \frac{\sqrt{\log d}}{\sqrt{d'}} \right) \ge 1 - \frac{1}{\text{poly}(d)}.$$

Also, for $\xi \sim \mathcal{N}(0, \frac{1}{d} \cdot I_{d \times d})$, when $\sigma \leq \frac{1}{\sqrt{d}}$ we have

$$\Pr_{\xi \sim \mathcal{N}(0, \frac{\sigma^2}{d} \cdot I_{d' \times d'})} \left(\|\xi\|_2 \lesssim \frac{\sqrt{\log d}}{\sqrt{d}} \right) \ge 1 - \frac{1}{\mathsf{poly}(d)}.$$

Notice that $\|Q^{-1}(Q(z)+\xi)-z\|_2 \le \kappa \|\xi\|$, we can set $\|\mu_i-\mu_j\| \gtrsim \kappa \frac{\sqrt{\log d}}{\sqrt{d}}$. Therefore, when $\|\mu_i-\mu_j\| \gtrsim \kappa \frac{\sqrt{\log d}}{\sqrt{d'}}$ we can combine the above two cases and have

$$\Pr_{z \sim \mathcal{N}(\mu_i, \frac{1}{d'} \cdot I_{d' \times d'}), \xi \sim \mathcal{N}(0, \frac{\sigma^2}{d} \cdot I_{d' \times d'})} \left(P_i(z) > P_j(Q^{-1}(Q(z) + \xi)) \right) \ge 1 - \frac{1}{\text{poly}(d)}.$$

Since $r \leq d$, we have

$$\Pr_{\bar{x} \sim \mathcal{P}_{\overline{\mathcal{X}}}, x \sim \mathcal{A}(\cdot | \bar{x})}(y(x) \neq y(\bar{x})) \ge 1 - \frac{1}{\mathsf{poly}(d)}.$$

We use the following lemma to give a lower bound for the sparest m-partition of the augmentation graph in Example 3.8.

Lemma C.2. In the setting of Theorem 3.9, for any k' > r and $\tau > 0$, we have

$$\rho_{k'} \ge \frac{c_{\tau/\kappa}}{18} \cdot \exp\left(-\frac{2c_{\sigma}\tau + \tau^2}{2\sigma^2/d}\right),$$

where

$$c_{\sigma} := \sigma \cdot \Phi_d^{-1}(\frac{2}{3})$$

with $\Phi_d(z) := \Pr_{\xi \sim \mathcal{N}(0, \frac{1}{d}I_{d \times d})}(\|\xi\|_2 \leq z)$, and

$$c_{\tau/\kappa} := \min_{p \in [0, \frac{3}{4}]} \frac{\Phi(\Phi^{-1}(p) + \tau\sqrt{d}/\kappa)}{p} - 1$$

with
$$\Phi(z) := \int_{-\infty}^{z} \frac{e^{-u^2/2}}{\sqrt{2\pi}} du$$
.

The proof of Lemma C.2 can be found in Section C.1. Now we give the proof of Example 3.9.

Proof of Theorem 3.9. The result on α is directly from Lemma C.1. By concentration inequality, there must exists some universal constant C>0 such that for any $d\geq C$, we have $1-\Phi_d(\sqrt{\frac{3}{2}})\leq \frac{1}{3}$. When this happens, we have $\Phi_d^{-1}(\frac{2}{3})\leq \sqrt{\frac{3}{2}}$. Since for $d\leq C$ we can just treat d as constant, we have $\Phi_d^{-1}(\frac{2}{3})\lesssim 1$. Set $\tau=\sigma/d$ in Lemma C.2, we have $\rho_{k'}\gtrsim \frac{\sigma}{\kappa\sqrt{d}}$. Set $k'=\lfloor k/2\rfloor$, we apply Theorem 3.7 and get the bound we need.

C.1 Proof of Lemma C.2

In this section we give a proof for Lemma C.2. We first introduce the following claim which states that for a given subset of augmented data, any two data close in L_2 norm cannot have a very different chance of being augmented into this set.

Claim C.3. In the setting of Theorem 3.9, given a set $S \subseteq \mathbb{R}^d$. If $x \in \mathbb{R}^d$ satisfies $\Pr(S|x) := \Pr_{\tilde{x} \sim \mathcal{A}(\cdot|x)}(\tilde{x} \in S) \geq \frac{2}{3}$. Then, for any x' such that $||x - x'||_2 \leq \tau$, we have

$$\Pr(S|x') \ge \frac{1}{3} \cdot \exp\left(-\frac{2c_{\sigma}\tau + \tau^2}{2\sigma^2}\right),$$

where

$$c_{\sigma} := \sigma \cdot \Phi_d^{-1}(\frac{2}{3}),$$

with $\Phi_d(z) := \Pr_{\xi \sim \mathcal{N}(0, \frac{1}{d} \cdot I_{d \times d})} (\|\xi\|_2 \le z).$

Proof of Claim C.3. By the definition of augmentation, we know

$$\Pr(S|x) = \mathbb{E}_{\xi \sim \mathcal{N}(0, \frac{\sigma^2}{\cdot} \cdot I_{d \times d})} \left[\mathbb{1} \left[x + \xi \in S \right] \right].$$

By the definition of c_{σ} , we have

$$\Pr_{\xi \sim \mathcal{N}(0, \frac{\sigma^2}{d} \cdot I_{d \times d})} (\|\xi\|_2 \le c_{\sigma}) = \frac{2}{3}.$$

Since $Pr(S|x) \ge \frac{2}{3}$ by assumption, we have

$$\mathbb{E}_{\xi \sim \mathcal{N}(0, \frac{\sigma^2}{d} \cdot I_{d \times d})} \left[P(S|x + \xi) \cdot \mathbb{1} \left[\|\xi\|_2 \le c_{\sigma} \right] \right] \ge \frac{1}{3}.$$

Now we can bound the quanity of our interest:

$$\Pr(S|x') = \frac{1}{(2\pi\sigma^{2}/d)^{d/2}} \int_{\xi} e^{-\frac{\|\xi\|_{2}^{2}}{2\sigma^{2}/d}} P(S|x'+\xi) d\xi$$

$$= \frac{1}{(2\pi\sigma^{2}/d)^{d/2}} \int_{\xi} e^{-\frac{\|\xi+x-x'\|_{2}^{2}}{2\sigma^{2}/d}} P(S|x+\xi) d\xi$$

$$\geq \frac{1}{(2\pi\sigma^{2}/d)^{d/2}} \int_{\xi} e^{-\frac{\|\xi+x-x'\|_{2}^{2}}{2\sigma^{2}/d}} P(S|x+\xi) \cdot \mathbb{1} [\|\xi\|_{2} \leq c_{\sigma}] d\xi$$

$$\geq \frac{1}{(2\pi\sigma^{2}/d)^{d/2}} \int_{\xi} e^{-\frac{2c_{\sigma}\tau+\tau^{2}+\|\xi\|_{2}^{2}}{2\sigma^{2}/d}} P(S|x+\xi) \cdot \mathbb{1} [\|\xi\|_{2} \leq c_{\sigma}] d\xi$$

$$= e^{-\frac{2c_{\sigma}\tau+\tau^{2}}{2\sigma^{2}/d}} \cdot \mathbb{E}_{\xi \sim \mathcal{N}(0, \frac{\sigma^{2}}{d}I_{d \times d})} [P(S|x+\xi) \cdot \mathbb{1} [\|\xi\|_{2} \leq c_{\sigma}]]$$

$$\geq \frac{1}{3} \cdot \exp\left(-\frac{2c_{\sigma}\tau+\tau^{2}}{2\sigma^{2}/d}\right).$$

We now give the proof of Lemma C.2.

Proof of Lemma C.2. Let $S_1, \dots, S_{k'}$ be the disjoint sets that gives $\rho_{k'}$ in Definition 3.4. First we notice that when k' > r, there must exist $t \in [k']$ such that for all $i \in [r]$, we have

$$\Pr_{x \sim P_i, \tilde{x} \sim \mathcal{A}(\cdot|x)} (\tilde{x} \in S_t) \le \frac{1}{2}.$$
 (26)

WLOG, we assume t = 1. So we know that

$$\rho_{k'} = \max_{i \in [k']} \phi_G(S_i) \ge \phi_G(S_1) \ge \min_{j \in [r]} \frac{\mathbb{E}_{x \sim P_j} \left[\Pr(S_1 | x) (1 - \Pr(S_1 | x)) \right]}{\mathbb{E}_{x \sim P_j} \left[\Pr(S_1 | x) \right]},\tag{27}$$

where

$$\Pr(S|x) := \Pr_{\tilde{x} \sim \mathcal{A}(\cdot|x)} (\tilde{x} \in S).$$

WLOG, we assume j = 1 minimizes the RHS of Equation (27), so we only need to prove

$$\frac{\mathbb{E}_{x \sim P_1} \left[\Pr(S_1 | x) (1 - \Pr(S_1 | x)) \right]}{\mathbb{E}_{x \sim P_1} \left[\Pr(S_1 | x) \right]} \ge \frac{c_{\tau/\kappa}}{18} \cdot \exp\left(-\frac{2c_\sigma \tau + \tau^2}{2\sigma^2/d} \right).$$

We define the following set

$$R := \left\{ x \middle| \Pr(S_1|x) \ge \frac{2}{3} \right\}.$$

Notice that

$$\mathbb{E}_{x \sim P_1} \left[\Pr(S_1 | x) \right] = \int_x P_1(x) \Pr(S_1 | x) dx$$

$$= \int_{x \in R} P_1(x) \Pr(S_1 | x) dx + \int_{x \notin R} P_1(x) \Pr(S_1 | x) dx. \tag{28}$$

We can consider the following two cases.

Case 1: $\int_{x \notin R} P_1(x) \Pr(S_1|x) dx \ge \frac{1}{2} \mathbb{E}_{x \sim P_1} \left[\Pr(S_1|x) \right].$

This is the easy case because we have

$$\mathbb{E}_{x \sim P_1} \left[\Pr(S_1 | x) (1 - \Pr(S_1 | x)) \right] \ge \int_{x \notin R} P_1(x) \Pr(S_1 | x) (1 - \Pr(S_1 | x)) dx$$

$$\ge \frac{1}{3} \int_{x \notin R} P_1(x) \Pr(S_1 | x) dx$$

$$\ge \frac{1}{6} \mathbb{E}_{x \sim P_1} \left[\Pr(S_1 | x) \right].$$

Case 2: $\int_{x \in R} P_1(x) \Pr(S_1|x) dx \ge \frac{1}{2} \mathbb{E}_{x \sim P_1} [\Pr(S_1|x)].$

Define neighbourhood of R as

$$N(R) := \left\{ x \middle| \|x - a\|_2 \le \tau \text{ for some } a \in R \right\}.$$

We have

$$\mathbb{E}_{x \sim P_1} \left[\Pr(S_1 | x) (1 - \Pr(S_1 | x)) \right] \ge \int_{x \in N(R) \setminus R} P_1(x) \Pr(S_1 | x) (1 - \Pr(S_1 | x)) dx$$
$$\ge \frac{1}{9} \cdot \exp\left(-\frac{2c_\sigma \tau + \tau^2}{2\sigma^2/d} \right) \cdot \int_{x \in N(R) \setminus R} P_1(x) dx,$$

where the second inequality is by Claim C.3. Notice that

$$\int_{x \in R} P_1(x) dx \le \frac{3}{2} \int_{x \in R} P_1(x) \Pr(S_1|x) dx \le \frac{3}{2} \int_x P_1(x) \Pr(S_1|x) dx \le \frac{3}{4},$$

where we use Equation (26). Define set $\widetilde{R} := Q^{-1}(R)$ be the set in the ambient space corresponding to R. Define

$$\widetilde{N}(\widetilde{R}) := \left\{ x' \in \mathbb{R}^{d'} \middle| \left\| x' - a \right\|_2 \le \frac{\tau}{\kappa} \text{ for some } a \in \widetilde{R} \right\}$$

Due to Q being κ -bi-lipschitz, it is easy to see $\widetilde{N}(\widetilde{R}) \subseteq Q^{-1}(N(R))$. According to the Gaussian isoperimetric inequality (Bobkov et al., 1997), we have

$$\int_{x \in N(R) \setminus R} P_1(x) dx \ge c_{\tau/\kappa} \int_{x \in R} P_1(x) dx,$$

where

$$c_{\tau/\kappa} := \min_{0 \leq p \leq 3/4} \frac{\Phi(\Phi^{-1}(p) + \tau \sqrt{d}/\kappa)}{p} - 1,$$

with $\Phi(\cdot)$ is the Gaussian CDF function defined as

$$\Phi(z) := \int_{-\infty}^{z} \frac{e^{-u^2/2}}{\sqrt{2\pi}} du.$$

So we have

$$\mathbb{E}_{x \sim P_1} \left[\Pr(S_1 | x) (1 - \Pr(S_1 | x)) \right] \ge \frac{c_{\tau/\kappa}}{9} \cdot \exp\left(-\frac{2c_{\sigma}\tau + \tau^2}{2\sigma^2/d} \right) \cdot \int_{x \in R} P_1(x) dx$$

$$\ge \frac{c_{\tau/\kappa}}{9} \cdot \exp\left(-\frac{2c_{\sigma}\tau + \tau^2}{2\sigma^2/d} \right) \cdot \int_{x \in R} P_1(x) \Pr(S_1 | x) dx$$

$$\ge \frac{c_{\tau/\kappa}}{18} \cdot \exp\left(-\frac{2c_{\sigma}\tau + \tau^2}{2\sigma^2/d} \right) \cdot \mathbb{E}_{x \sim P_1} \left[\Pr(S_1 | x) \right].$$

By Equation (28), either case 1 or case 2 holds. Combining case 1 and case 2, we have

$$\frac{\mathbb{E}_{x \sim P_1} \left[\Pr(S_1 | x) (1 - \Pr(S_1 | x)) \right]}{\mathbb{E}_{x \sim P_1} \left[\Pr(S_1 | x) \right]} \ge \min \left\{ \frac{1}{6}, \frac{c_{\tau/\kappa}}{18} \cdot \exp\left(-\frac{2c_{\sigma}\tau + \tau^2}{2\sigma^2/d} \right) \right\}
= \frac{c_{\tau/\kappa}}{18} \cdot \exp\left(-\frac{2c_{\sigma}\tau + \tau^2}{2\sigma^2/d} \right).$$

D Proofs for Section 4

D.1 Proof of Theorem 4.1

We restate the empirical spectral contrastive loss defined in Section 4 as follows:

Definition D.1 (Empirical spectral contrastive loss). Consider a dataset $\widehat{\mathcal{X}} = \{\bar{x}_1, \bar{x}_2, \cdots, \bar{x}_n\}$ containing n data points i.i.d. sampled from $\mathcal{P}_{\overline{\mathcal{X}}}$. Let $\widehat{\mathcal{P}}_{\mathcal{X}}$ be the uniform distribution over $\widehat{\mathcal{X}}$. Let $\widehat{\mathcal{P}}_{\bar{x},\bar{x}'}$ be the uniform distribution over data pairs (\bar{x}_i, \bar{x}_j) where $i \neq j$. We define the empirical spectral contrastive loss of a feature extractor f as

$$\widehat{\mathcal{L}}_f(:) = -2\mathbb{E}_{\substack{\bar{x} \sim \hat{\mathcal{P}}_{\mathcal{X}}, \\ x \sim \mathcal{A}(\cdot \mid \bar{x}), x' \sim \mathcal{A}(\cdot \mid \bar{x})}} \left[f(x)^\top f(x') \right] + \mathbb{E}_{\substack{(\bar{x}, \bar{x}') \sim \hat{\mathcal{P}}_{\bar{x}, \bar{x}'}, \\ x \sim \mathcal{A}(\cdot \mid \bar{x}), x' \sim \mathcal{A}(\cdot \mid \bar{x})}} \left[\left(f(x)^\top f(x') \right)^2 \right].$$

The following claim shows that $\widehat{\mathcal{L}}_n(f)$ is an unbiased estimator of population spectral contrastive loss.

Claim D.2. $\widehat{\mathcal{L}}_n(f)$ is an unbiased estimator of $\mathcal{L}(f)$, i.e.,

$$\mathbb{E}_{\widehat{\mathcal{X}}}\left[\widehat{\mathcal{L}}_n(f)\right] = \mathcal{L}(f).$$

Proof. This is because

$$\mathbb{E}_{\widehat{\mathcal{X}}}\left[\widehat{\mathcal{L}}_{n}(f)\right] = -2 \cdot \mathbb{E}_{\widehat{\mathcal{X}}}\left[\mathbb{E}_{\substack{\bar{x} \sim \hat{\mathcal{P}}_{\mathcal{X}}, \\ x \sim \mathcal{A}(\cdot | \bar{x}), x' \sim \mathcal{A}(\cdot | \bar{x})}}\left[f(x)^{\top} f(x')\right]\right] + \mathbb{E}_{\widehat{\mathcal{X}}}\left[\mathbb{E}_{\substack{(\bar{x}, \bar{x}') \sim \hat{\mathcal{P}}_{\bar{x}, \bar{x}'}, \\ x \sim \mathcal{A}(\cdot | \bar{x}), x' \sim \mathcal{A}(\cdot | \bar{x}')}}\left[\left(f(x)^{\top} f(x')\right)^{2}\right]\right]$$

$$= -2\mathbb{E}_{\substack{\bar{x} \sim \mathcal{P}_{\overline{\mathcal{X}}}, \\ x \sim \mathcal{A}(\cdot | \bar{x}), x' \sim \mathcal{A}(\cdot | \bar{x}')}}\left[f(x)^{\top} f(x')\right] + \mathbb{E}_{\substack{\bar{x} \sim \mathcal{P}_{\overline{\mathcal{X}}}, \bar{x}' \sim \mathcal{P}_{\overline{\mathcal{X}}}, \\ x \sim \mathcal{A}(\cdot | \bar{x}'), x' \sim \mathcal{A}(\cdot | \bar{x}')}}\left[\left(f(x)^{\top} f(x')\right)^{2}\right] = \mathcal{L}(f).$$

To make use of the Radmacher complexity theory, we need to write the empirical loss as the sum of i.i.d. terms, which is achieved by the following sub-sampling scheme:

Definition D.3. Given dataset $\widehat{\mathcal{X}}$, we sample a subset of tuples as follows: first sample a permutation $\pi:[n]\to[n]$, then we sample tuples $S=\{(z_i,z_i^+,z_i')\}_{i=1}^{n/2}$ as follows:

$$z_{i} \sim \mathcal{A}(\cdot | \bar{x}_{\pi(2i-1)}),$$

$$z_{i}^{+} \sim \mathcal{A}(\cdot | \bar{x}_{\pi(2i-1)}),$$

$$z'_{i} \sim \mathcal{A}(\cdot | \bar{x}_{\pi(2i)}).$$

We define the following loss on S:

$$\widehat{\mathcal{L}}_{S}(f) := \frac{1}{n/2} \sum_{i=1}^{n/2} \left[\left(f(z_{i})^{\top} f(z_{i}') \right)^{2} - 2f(z_{i})^{\top} f(z_{i}^{+}) \right].$$

It is easy to see that $\widehat{\mathcal{L}}_S(f)$ is an unbiased estimator of $\widehat{\mathcal{L}}_n(f)$:

Claim D.4. For given $\widehat{\mathcal{X}}$, if we sample S as above, we have:

$$\mathbb{E}_S\left[\widehat{\mathcal{L}}_S(f)\right] = \widehat{\mathcal{L}}_f(.)$$

Proof. This is obvious by the definition of $\widehat{\mathcal{L}}_S(f)$ and $\widehat{\mathcal{L}}_n(f)$.

The following lemma reveals the relationship between the Rademacher complexity of feature extractors and the Rademacher complexity of the loss defined on tuples:

Lemma D.5. Let \mathcal{F} be a hypothesis class of feature extractors from \mathcal{X} to \mathbb{R}^k . Assume $||f(x)||_{\infty} \leq \kappa$ for all $x \in \mathcal{X}$. For $i \in [k]$, define $f_i : \mathcal{X} \to \mathbb{R}$ be the function such that $f_i(x)$ is the i-th dimension of f(x). Let \mathcal{F}_i be the hypothesis containing f_i for all $f \in \mathcal{F}$. For $m \in \mathcal{Z}^+$, let $\widehat{\mathcal{R}}_m(\mathcal{F}_i)$ be the maximal possible empirical Rademacher complexity of \mathcal{F}_i over m data:

$$\widehat{\mathcal{R}}_m(\mathcal{F}_i) := \max_{\{x_1, x_2, \dots, x_m\}} \mathbb{E}_{\sigma} \left[\sup_{f_i \in \mathcal{F}_i} \left(\frac{1}{m} \sum_{j=1}^m \sigma_j f_i(x_j) \right) \right],$$

where x_1, x_2, \dots, x_m are in \mathcal{X} , and σ is a uniform random vector in $\{-1, 1\}^m$. Then, the empirical Rademacher complexity on any m tuples $\{(z_i, z_i^+, z_i')\}_{i=1}^m$ can be bounded by

$$\mathbb{E}_{\sigma} \left[\sup_{f \in \mathcal{F}} \left(\frac{1}{m} \sum_{j=1}^{m} \sigma_j \left(\left(f(z_j)^{\top} f(z_j') \right)^2 - 2f(z_j)^{\top} f(z_j^+) \right) \right) \right] \leq (16k^2 \kappa^2 + 16k \kappa) \cdot \max_{i \in [k]} \widehat{\mathcal{R}}_m(\mathcal{F}_i).$$

Proof.

$$\mathbb{E}_{\sigma} \left[\sup_{f \in \mathcal{F}} \left(\frac{1}{m} \sum_{j=1}^{m} \sigma_{j} \left(\left(f(z_{j})^{\top} f(z_{j}') \right)^{2} - 2f(z_{j})^{\top} f(z_{j}^{+}) \right) \right) \right] \\
\leq \mathbb{E}_{\sigma} \left[\sup_{f \in \mathcal{F}} \left(\frac{1}{m} \sum_{j=1}^{m} \sigma_{j} \left(f(z_{j})^{\top} f(z_{j}') \right)^{2} \right) \right] + 2\mathbb{E}_{\sigma} \left[\sup_{f \in \mathcal{F}} \left(\frac{1}{m} \sum_{j=1}^{m} \sigma_{j} f(z_{j})^{\top} f(z_{j}^{+}) \right) \right] \\
\leq 2k\kappa \mathbb{E}_{\sigma} \left[\sup_{f \in \mathcal{F}} \left(\frac{1}{m} \sum_{j=1}^{m} \sigma_{j} f(z_{j})^{\top} f(z_{j}') \right) \right] + 2\mathbb{E}_{\sigma} \left[\sup_{f \in \mathcal{F}} \left(\frac{1}{m} \sum_{j=1}^{m} \sigma_{j} f(z_{j})^{\top} f(z_{j}^{+}) \right) \right] \\
\leq (2k^{2}\kappa + 2k) \max_{\substack{z_{1}, z_{2}, \dots, z_{m} \\ z_{1}, z_{2}, \dots, z_{m}}} \max_{i \in [k]} \mathbb{E}_{\sigma} \left[\sup_{f_{i} \in \mathcal{F}_{i}} \left(\frac{1}{m} \sum_{j=1}^{m} \sigma_{j} f_{i}(z_{j}) f_{i}(z_{j}') \right) \right],$$

here the second inequality is by Talagrand's lemma. Notice that for any $z_1, z_2 \cdots z_m$ and z'_1, z'_2, \cdots, z'_m in \mathcal{X} and any $i \in [k]$ we have

$$\mathbb{E}_{\sigma} \left[\sup_{f_{i} \in \mathcal{F}_{i}} \left(\frac{1}{m} \sum_{j=1}^{m} \sigma_{j} f_{i}(z_{j}) f_{i}(z'_{j}) \right) \right]$$

$$\leq \frac{1}{2} \mathbb{E}_{\sigma} \left[\sup_{f_{i} \in \mathcal{F}_{i}} \left(\frac{1}{m} \sum_{j=1}^{m} \sigma_{j} \left(f_{i}(z_{j}) + f_{i}(z'_{j}) \right)^{2} \right) \right] + \frac{1}{2} \mathbb{E}_{\sigma} \left[\sup_{f_{i} \in \mathcal{F}_{i}} \left(\frac{1}{m} \sum_{j=1}^{m} \sigma_{j} \left(f_{i}(z_{j}) - f_{i}(z'_{j}) \right)^{2} \right) \right]$$

$$\leq 4\kappa \mathbb{E}_{\sigma} \left[\sup_{f_{i} \in \mathcal{F}_{i}} \left(\frac{1}{m} \sum_{j=1}^{m} \sigma_{j} f_{i}(z_{j}) \right) \right] + 4\kappa \mathbb{E}_{\sigma} \left[\sup_{f_{i} \in \mathcal{F}_{i}} \left(\frac{1}{m} \sum_{j=1}^{m} \sigma_{j} f_{i}(z'_{j}) \right) \right],$$

where the first inequaltiy is by Talagrand's lemma. Combine these two equations and we get:

$$\mathbb{E}_{\sigma} \left[\sup_{f \in \mathcal{F}} \left(\frac{1}{m} \sum_{j=1}^{m} \sigma_{j} \left(\left(f(z_{j})^{\top} f(z_{j}') \right)^{2} - 2f(z_{j})^{\top} f(z_{j}^{+}) \right) \right) \right]$$

$$\leq (16k^{2} \kappa^{2} + 16k\kappa) \max_{z_{1}, z_{2}, \dots, z_{m}} \max_{i \in [k]} \mathbb{E}_{\sigma} \left[\sup_{f_{i} \in \mathcal{F}_{i}} \left(\frac{1}{m} \sum_{j=1}^{m} \sigma_{j} f_{i}(z_{j}) \right) \right].$$

Proof of Theorem 4.1. By Claim D.2 and Claim D.4, we know that $\mathbb{E}_S[\widehat{\mathcal{L}}_S(f)] = \mathcal{L}(f)$, where S is sampled by first sampling $\widehat{\mathcal{X}}$ then sample S according to Definition D.3. Notice that when $\widehat{\mathcal{X}}$ contains n i.i.d. samples natural data, the set of random tuples S contains n i.i.d tuples. Therefore, we can apply generalization bound with Rademacher complexity to get a uniform convergence bound. In particular, by Lemma D.5 and notice the fact that $\left(f(z_j)^{\top}f(z_j')\right)^2 - 2f(z_j)^{\top}f(z_j^+)$ always take values in range $[-2k\kappa^2, 2k\kappa^2 + k^2\kappa^4]$, we apply standard generalization analysis based on Rademacher complexity and get: with probability at least $1 - \delta^2/4$ over the randomness of $\widehat{\mathcal{X}}$ and S, we have for any $f \in \mathcal{F}$,

$$\mathcal{L}(f) \le \widehat{\mathcal{L}}_S(f) + (32k^2\kappa^2 + 32k\kappa) \max_{i \in [k]} \widehat{\mathcal{R}}_{n/2}(\mathcal{F}_i) + (4k\kappa^2 + k^2\kappa^4) \cdot \sqrt{\frac{4\log 2/\delta}{n}}.$$
 (29)

33

This means with probability at least $1-\delta/2$ over random $\widehat{\mathcal{X}}$, we have: with probability at least $1-\delta/2$ over random tuples S conditioned on $\widehat{\mathcal{X}}$, Equation (29) holds. Since both $\mathcal{L}(f)$ and $\widehat{\mathcal{L}}_n(f)$ take value in range $[-2k\kappa^2, 2k\kappa^2 + k^2\kappa^4]$, we have: with probability at least $1-\delta/2$ over random $\widehat{\mathcal{X}}$, we have for any $f \in \mathcal{F}$,

$$\mathcal{L}(f) \leq \widehat{\mathcal{L}}_n(f) + (32k^2\kappa^2 + 32k\kappa) \cdot \max_{i \in [k]} \widehat{\mathcal{R}}_{n/2}(\mathcal{F}_i) + (4k\kappa^2 + k^2\kappa^4) \cdot \left(\sqrt{\frac{4\log 2/\delta}{n}} + \frac{\delta}{2}\right).$$

Since negating the functions in a function class doesn't change its Rademacher complexity, we also have the other direction: with probability at least $1 - \delta/2$ over random $\widehat{\mathcal{X}}$, we have for any $f \in \mathcal{F}$,

$$\mathcal{L}(f) \ge \widehat{\mathcal{L}}_n(f) - (32k^2\kappa^2 + 32k\kappa) \cdot \max_{i \in [k]} \widehat{\mathcal{R}}_{n/2}(\mathcal{F}_i) + (4k\kappa^2 + k^2\kappa^4) \cdot \left(\sqrt{\frac{4\log 2/\delta}{n}} + \frac{\delta}{2}\right).$$

Combine them together we get the excess risk bound: with probability at least $1 - \delta$, we have

$$\mathcal{L}(\hat{f}) \leq \mathcal{L}(f_{\mathcal{F}}^*) + \left(64k^2\kappa^2 + 64k\kappa\right) \cdot \max_{i \in [k]} \widehat{\mathcal{R}}_{n/2}(\mathcal{F}_i) + \left(8k\kappa^2 + 2k^2\kappa^4\right) \cdot \left(\sqrt{\frac{4\log 2/\delta}{n}} + \frac{\delta}{2}\right),$$

where \hat{f} is minimizer of $\widehat{\mathcal{L}}_n(f)$ in \mathcal{F} and $f_{\mathcal{F}}^*$ is minimizer of $\mathcal{L}(f)$ in \mathcal{F} . Set $c_1 = 64k^2\kappa^2 + 64k\kappa$ and $c_2 = 16k\kappa^2 + 4k^2\kappa^4$ and notice that $\max_{i \in [k]} \widehat{\mathcal{R}}_{n/2}(\mathcal{F}_i) = \widehat{\mathcal{R}}_{n/2}(\mathcal{F})$ finishes the proof.

D.2 Generalization bound for spectral contrastive learning with deep neural networks

In this section, we examplify Theorem 4.1 with the norm-contralled Rademacher complexity bound introduced in (Golowich et al., 2018), which gives the following theorem.

Theorem D.6. Assume \mathcal{X} is a subset of Euclidean space \mathbb{R}^d and $||x||_2 \leq C_x$ for any $x \in \mathcal{X}$. Let \mathcal{F} be a hypothesis class of norm-contralled l-layer deep neural networks defined as

$$\{x \to P_{\kappa}(W_l \sigma(W_{l-1} \sigma(\cdots \sigma(W_1 x)))) : ||W_i||_F \le C_{w,i}\}$$

where $\sigma(\cdot)$ is element-wise ReLU activation, $P_{\kappa}(\cdot)$ is element-wise projection to interval $[-\kappa, \kappa]$ for some $\kappa > 0$, $C_{w,i}$ is the norm bound of the i-th layer, W_l has k rows and W_l has d columns. Then, with probability at least $1 - \delta$ over randomness of a dataset with size 2n, we have

$$\mathcal{L}(\hat{f}) \le \mathcal{L}_{\mathcal{F}}^* + c_1 \cdot \frac{C_x C_w \sqrt{l}}{\sqrt{n}} + c_2 \cdot \left(\sqrt{\frac{\log 1/\delta}{n}} + \delta\right),$$

where \hat{f} is the minimizer of $\widehat{\mathcal{L}}_{2n}(f)$ in \mathcal{F} , $\mathcal{L}_{\mathcal{F}}^*$ is the minimal $\mathcal{L}(f)$ achievable by any function $f \in \mathcal{F}$, $C_w := \prod_{i=1}^l C_{w,i}$, constants $c_1 \lesssim k^2 \kappa^2 + k \kappa$ and $c_2 \lesssim k \kappa^2 + k^2 \kappa^4$.

Proof of Theorem D.6. Consider the following hypothesis class of real-valued neural networks:

$$\mathcal{F}_{\text{real}} \triangleq \left\{ x \to \widehat{W}_{l} \sigma(W_{l-1} \sigma(\cdots \sigma(W_{1} x))) : \|W_{i}\|_{F} \le C_{w,i} \right\}$$

where $\sigma(\cdot)$ is element-wise ReLU activation and $C_{w,i}$ is the norm bound of the *i*-th layer defined in the theorem, W_l has k rows and \widehat{W}_1 is a vector. By Theorem 1 of (Golowich et al., 2018), we have

$$\widehat{\mathcal{R}}_n\left(\mathcal{F}_{\text{real}}\right) \leq \frac{C_x(\sqrt{2\log(2)l}+1)C_w}{\sqrt{n}}.$$

Let the projection version of this hyposis class be:

$$\mathcal{F}_{\text{real+proj}} \triangleq \left\{ x \to P_{\kappa}(\widehat{W}_{l}\sigma(W_{l-1}\sigma(\cdots\sigma(W_{1}x)))) : \|W_{i}\|_{F} \leq C_{w,i} \right\},\,$$

where $P_{\kappa}(\cdot)$ projects a real number into interval $[-C_w, C_w]$. Notice that $P_{\kappa}(\cdot)$ is 1-Lipschitz, by Telegrand's lemma we have

$$\widehat{\mathcal{R}}_n\left(\mathcal{F}_{\text{real+proj}}\right) \le \frac{C_x(\sqrt{2\log(2)l}+1)C_w}{\sqrt{n}}.$$

For each $i \in [k]$, define function $f_i : \mathcal{X} \to \mathbb{R}$ such that $f_i(x)$ is the i-th dimension of f(x), define \mathcal{F}_i be the hypothesis class including all f_i for $f \in \mathcal{F}$. Then when \mathcal{F} is the composition of deep neural networks and projection function as defined in the theorem, it is obvious to see that $\mathcal{F}_i = \mathcal{F}_{\text{real+proj}}$ for all $i \in [k]$. Therefore, by Theorem 4.1 we have

$$\mathcal{L}(\hat{f}) \le \mathcal{L}_{\mathcal{F}}^* + c_1 \cdot \frac{C_x(\sqrt{2\log(2)l} + 1)C_w}{\sqrt{n}} + c_2 \cdot \left(\sqrt{\frac{\log 2/\delta}{n}} + \delta\right),$$

and absorbing the constants into c_1 finishes the proof.

D.3 Proof of Theorem 4.2

In this section we give the proof of Theorem 4.2. We first introduce the following definitions of ϵ -optimal minimizers of matrix approximation loss and population spectral contrastive loss:

Definition D.7. We say a function \hat{f}_{mf} is ϵ -optimal minimizer of matrix approximation loss \mathcal{L}_{mf} if

$$\mathcal{L}_{\mathrm{mf}}(\widehat{F}_{\mathrm{mf}}) \leq \min_{F} \mathcal{L}_{\mathrm{mf}}(F) + \epsilon,$$

where \hat{F}_{mf} is \hat{f}_{mf} written in the matrix form. We say a function \hat{f} is ϵ -optimal minimizer of spectral contrastive loss \mathcal{L} if

$$\mathcal{L}(\hat{f}) \le \min_{f} \mathcal{L}(f) + \epsilon.$$

We introduce the following generalized version of Theorem B.3, which captures the main effects of error in the representation.

Theorem D.8. [Generalization of Theorem B.3] Assume the set of augmented data \mathcal{X} is finite. Let λ_i be the i-th smallest eigenvalue of the normalize laplacian matrix. Let $\hat{f} \in \arg\min_{f:\mathcal{X} \to \mathbb{R}^k}$ be a ϵ -optimal minimizer of the spectral contrastive loss function $\mathcal{L}(f)$ with $k \in \mathcal{Z}^+$. Then, for any labeling function $\hat{y}: \mathcal{X} \to [r]$ there exists a linear probe $\hat{B} \in \mathbb{R}^{r \times k}$ such that

$$\Pr_{\bar{x} \sim \mathcal{P}_{\overline{\mathcal{X}}}, x \sim \mathcal{A}(\cdot | \bar{x})} \left(g_{\hat{f}, \widehat{B}}(x) \neq y(\bar{x}) \right) \leq \min_{1 \leq k' \leq k} \left(\frac{2\phi^{\hat{y}}}{\lambda_{k'+1}} + \frac{4k'\epsilon}{(\lambda_{k+1} - \lambda_{k'})^2} \right) + \Delta(y, \hat{y}),$$

where $\phi^{\hat{y}}$ and $\Delta(y, \hat{y})$ are defined in Equations 15 and 16 respectively.

The proof of lemma D.8 is deferred to Section D.4.

Now we are ready to prove Theorem 4.2 using Theorem D.8.

Proof of Theorem 4.2. In Theorem D.8 we let $k' = \lfloor \frac{3}{4}k \rfloor$ on the RHS of the bound and get: for any $\hat{y}: \mathcal{X} \to [r]$ there exists $\hat{B} \in \mathbb{R}^{r \times k}$ such that

$$\Pr_{x \sim \mathcal{P}_{\overline{\mathcal{X}}}, \tilde{x} \sim \mathcal{A}(\cdot | x)} \left(g_{\hat{f}, \widehat{B}}(\tilde{x}) \neq y(x) \right) \leq \frac{2\phi^{\hat{y}}}{\lambda_{|\frac{3}{4}k|+1}} + \frac{3k\epsilon}{(\lambda_{k+1} - \lambda_{|\frac{3}{4}k|})^2} + \Delta(y, \hat{y}).$$

Let S_1, S_2, \cdots, S_r be the partition of $\mathcal X$ induced by the classifier g in Assumption 3.5. Define function $\hat y: \mathcal X \to [r]$ as follows: for an augmented datapoint $x \in \mathcal X$, we use function $\hat y(x)$ to represent the index of set that x is in, i.e., $x \in S_{\hat y(x)}$. Then by Lemma B.5 we have $\phi^{\hat y} \leq 2\alpha$ and $\Delta(y,\hat y) \leq \alpha$. In Lemma B.4 let $(1+\zeta)t = \lfloor \frac{3}{4}k \rfloor + 1$ and $t = \lfloor \frac{k}{2} \rfloor$, then there is $\zeta \geq 0.5$, so we have: there exists a partition $S_1, \cdots, S_{\lfloor \frac{k}{2} \rfloor} \subset \mathcal X$ such that $\phi_G(S_i) \lesssim \sqrt{\lambda_{\lfloor \frac{3}{4}k \rfloor + 1} \log{(k)}}$ for $\forall i \in [\lfloor \frac{k}{2} \rfloor]$. By Definition 3.4, we have $\rho_{\lfloor \frac{k}{2} \rfloor} \lesssim \sqrt{\lambda_{\lfloor \frac{3}{4}k \rfloor + 1} \log{(k)}}$, which leads to $\frac{1}{\lambda_{\lfloor \frac{3}{4}k \rfloor + 1}} \lesssim \frac{\log(k)}{\rho_{\lfloor \frac{k}{2} \rfloor}^2}$. So we have

$$\Pr_{\bar{x} \sim \mathcal{P}_{\overline{x}}, x \sim \mathcal{A}(\cdot | \bar{x})} \left(g_{\hat{f}, \widehat{B}}(x) \neq y(\bar{x}) \right) \lesssim \frac{\alpha}{\rho_{\lfloor \frac{k}{2} \rfloor}^2} \cdot \log(k) + \frac{k\epsilon}{(\lambda_{k+1} - \lambda_{\lfloor \frac{3}{4}k \rfloor})^2}$$

$$\lesssim \frac{\alpha}{\rho_{\lfloor \frac{k}{2} \rfloor}^2} \cdot \log(k) + \frac{k\epsilon}{(\lambda_k - \lambda_{\lfloor \frac{3}{4}k \rfloor})^2}.$$

Notice that by the definition of ensembled linear probe predictor, $\bar{g}_{\hat{f},\widehat{B}}(\bar{x}) \neq y(\bar{x})$ happens only if more than half of the augmentations of \bar{x} predicts differently from $y(\bar{x})$, so we have $\Pr_{\bar{x}\sim\mathcal{P}_{\overline{x}}}\left(\bar{g}_{\hat{f},\widehat{B}}\neq y(\bar{x})\right)\leq 2\Pr_{\bar{x}\sim\mathcal{P}_{\overline{x}},x\sim\mathcal{A}(\cdot|\bar{x})}\left(g_{\hat{f},\widehat{B}}(x)\neq y(\bar{x})\right)$ which finishes the proof.

D.4 Proof of Theorem D.8

In this section, we give the proof for Theorem D.8.

Lemma D.9 (Generalization of Lemma B.8). Let \hat{F}_{mf} be the matrix form of a feature extractor $\hat{f}_{mf}: \mathcal{X} \to \mathbb{R}^k$. Then, \hat{F}_{mf} is a ϵ -optimal minimizer of $\mathcal{L}_{mf}(F)$ if and only if

$$\hat{f}(x) := \frac{1}{\sqrt{w_x}} \cdot \hat{f}_{\rm mf}(x)$$

is a ϵ -optimal minimizer of spectral contrastive loss $\mathcal{L}(f)$.

Proof of Lemma D.9. The proof follows the proof of Lemma B.8.

We will use the following important lemma about ϵ -optimal minimizer of \mathcal{L}_{mf} :

Lemma D.10. Let λ_i be the i-th minimal eigenvalue of the normalized Laplacian matrix L with corresponding unit-norm eigenvector v_i . Let $f: \mathcal{X} \to \mathbb{R}^k$ be ϵ -optimal minimizer of \mathcal{L}_{mf} where $\epsilon < (1 - \lambda_k)^2$. Let $F \in \mathbb{R}^{N \times k}$ be the matrix form of f, where $N = |\mathcal{X}|$. Let $\Pi_f^{\perp} v_i$ be the projection of v_i onto the subspace orthogonal to the column span of F. Then, for $i \leq k$ we have

$$\left\| \Pi_f^{\perp} v_i \right\|_2^2 \le \frac{\epsilon}{(\lambda_{k+1} - \lambda_i)^2}.$$

Proof. For function f with matrix form F, we overload notation $\mathcal{L}_{mf}(\cdot)$ and use $\mathcal{L}_{mf}(f)$ to represent $\mathcal{L}_{mf}(F)$.

We first prove that the column rank of f is k. If the column rank of f is less than k, then there must exists some function $f': \mathcal{X} \to \mathbb{R}^{k-1}$ such that $\mathcal{L}_{\mathrm{mf}}(f') = \mathcal{L}_{\mathrm{mf}}(f)$. According to the Eckart–Young–Mirsky Theorem, we have $\min_{f:\mathcal{X}\to\mathbb{R}^k}\mathcal{L}_{\mathrm{mf}}(f) = \sum_{j=k+1}^N (1-\lambda_j)^2$ and $\min_{f:\mathcal{X}\to\mathbb{R}^{k-1}}\mathcal{L}_{\mathrm{mf}}(f) = \sum_{j=k}^N (1-\lambda_j)^2$. Therefore, $\mathcal{L}_{\mathrm{mf}}(f) = \mathcal{L}_{\mathrm{mf}}(f') \geq (1-\lambda_k)^2 + \min_{f:\mathcal{X}\to\mathbb{R}^k}\mathcal{L}_{\mathrm{mf}}(f)$, contradicting with $\epsilon < (1-\lambda_k)^2$. As a result, the column rank of f has to be k.

Recall normalized adjacency matrix $\overline{A}=I-L$. We use \overline{A}_i to denote the i-th column of \overline{A} . We use \widehat{A} to denote matrix FF^{\top} and \widehat{A}_i to denote the i-th column of \widehat{A} . Let z_1, \cdots, z_k be unit-norm orthogonal vectors in the column span of F. Since the column span of \widehat{A} is the same as the column span of F, we know columns of \widehat{A} are in $span\{z_1, \cdots, z_k\}$. Let z_{k+1}, \cdots, z_N be unit-norm orthogonal vectors such that together with z_1, \cdots, z_k they form an orthonormal basis of \mathbb{R}^N . We use Π_f and Π_f^{\perp} to denote matrices $\sum_{j=1}^k z_j z_j^{\top}$ and $\sum_{j=k+1}^N z_j z_j^{\top}$ respectively, then for any vector $v \in \mathbb{R}^N$, vectors $\Pi_f v$ are the projections of v onto the column span of f and its orthogonal space respectively.

We first give a lower bound of $\mathcal{L}_{mf}(f)$ as follows:

$$\mathcal{L}_{\mathrm{mf}}(f) = \left\| \overline{A} - \widehat{A} \right\|_{F}^{2} = \sum_{j=1}^{N} \left\| \overline{A}_{j} - \widehat{A}_{j} \right\|_{2}^{2} \ge \sum_{j=1}^{N} \left\| \overline{A}_{j} - \Pi_{f} \overline{A}_{j} \right\|_{2}^{2}$$

$$= \sum_{j=1}^{N} \left\| \overline{A}_{j} - \left(\sum_{t=1}^{k} z_{t} z_{t}^{\top} \right) \overline{A}_{j} \right\|_{2}^{2} = \sum_{j=1}^{N} \left\| \left(\sum_{t=k+1}^{N} z_{t} z_{t}^{\top} \right) \overline{A}_{j} \right\|_{2}^{2}$$

$$= \left\| \left(\sum_{t=k+1}^{N} z_{t} z_{t}^{\top} \right) \overline{A} \right\|_{F}^{2} = \left\| \Pi_{f}^{\perp} \overline{A} \right\|_{F}^{2}.$$

where the first equality is by definition of $\mathcal{L}_{\mathrm{mf}}(f)$, the second equality is by writing the Frobenius norm square as the sum of column norm square, the inequality is because \widehat{A}_j must be in the span of z_1, \dots, z_k while $\Pi_f \overline{A}_j$ is the vector in this span that is closest to \overline{A}_j , the third equality is writing the projection function in the matrix form, the fourth equality is because $z_1, \dots z_d$ are an orthonormal basis, the fifth equality is rewriting to Frobenius norm, and the last equality is by definition of Π_f^{\perp} .

Notice that

$$\left\| \Pi_f^{\perp} \overline{A} \right\|_F^2 = Tr \left(\overline{A}^{\top} \Pi_f^{\perp} \overline{A} \right) = Tr \left(\overline{A}^{\top} \Pi_f^{\perp} \overline{A} \right) = Tr \left(\overline{A} \overline{A}^{\top} \Pi_f^{\perp} \right).$$

We can rewrite the above lower bound as

$$\mathcal{L}_{\mathrm{mf}}(f) \geq Tr\left(\overline{A}\overline{A}^{\top}\Pi_{f}^{\perp}\right) = Tr\left(\sum_{j=1}^{N} (1-\lambda_{j})^{2} v_{j} v_{j}^{\top} \sum_{t=k+1}^{N} z_{t} z_{t}^{\top}\right) = \sum_{j=1}^{N} \sum_{t=k+1}^{N} (1-\lambda_{j})^{2} \langle v_{j}, z_{t} \rangle^{2}.$$

We define variable $S_j \triangleq \sum_{t=1}^j \sum_{l=k+1}^d \langle v_t, z_l \rangle^2$ for any $j \in [N]$. Also denote $\lambda_{d+1} = 1$. We have the following equality:

$$\sum_{j=1}^{N} \sum_{t=k+1}^{N} (1 - \lambda_j)^2 \langle v_j, z_t \rangle^2 = \sum_{j=1}^{N} \left((1 - \lambda_j)^2 - (1 - \lambda_{j+1})^2 \right) S_j.$$

Notice that $S_j \geq 0$ and also when $i \leq j \leq k$, we have $S_j \geq \left\| \prod_{j=1}^{L} v_i \right\|_{2}^{2}$, we have

$$\sum_{j=1}^{N} \sum_{t=k+1}^{N} (1-\lambda_j)^2 \langle v_j, z_t \rangle^2 \ge \left((1-\lambda_i)^2 - (1-\lambda_{k+1})^2 \right) \left\| \Pi_f^{\perp} v_i \right\|_2^2 + \sum_{j=k+1}^{N} \left((1-\lambda_j)^2 - (1-\lambda_{j+1})^2 \right) S_j,$$

where we replace every S_j with 0 when j < k, replace S_j with $\left\| \Pi_f^{\perp} v_i \right\|_2^2$ when $i \leq j \leq k$, and keep S_j when $j \geq k+1$. Now notice that

$$S_N = \sum_{t=1}^N \sum_{l=k+1}^N \langle v_t, z_l \rangle^2 = \sum_{l=k+1}^N \sum_{t=1}^N \langle v_t, z_l \rangle^2 = \sum_{l=k+1}^N ||z_l||_2^2 = N - k,$$

and also

$$S_{j+1} - S_j = \sum_{l=k+1}^{N} \langle v_{j+1}, z_l \rangle^2 \le \sum_{l=1}^{N} \langle v_{j+1}, z_l \rangle^2 = 1,$$

there must be $S_j \ge j - k$ when $j \ge k + 1$. So we have

$$\begin{split} &\sum_{j=1}^{N} \sum_{t=k+1}^{N} (1 - \lambda_{j})^{2} \langle v_{j}, z_{t} \rangle^{2} \\ &\geq \left((1 - \lambda_{i})^{2} - (1 - \lambda_{k+1})^{2} \right) \left\| \Pi_{f}^{\perp} v_{i} \right\|_{2}^{2} + \sum_{j=k+1}^{N} \left((1 - \lambda_{j})^{2} - (1 - \lambda_{j+1})^{2} \right) (j - k) \\ &= \left((1 - \lambda_{i})^{2} - (1 - \lambda_{k+1})^{2} \right) \left\| \Pi_{f}^{\perp} v_{i} \right\|_{2}^{2} + \sum_{j=k+1}^{N} (1 - \lambda_{j})^{2} \\ &= \left((1 - \lambda_{i})^{2} - (1 - \lambda_{k+1})^{2} \right) \left\| \Pi_{f}^{\perp} v_{i} \right\|_{2}^{2} + \mathcal{L}_{mf}(f_{pop}^{*}), \end{split}$$

where f_{pop}^* is the minimizer of \mathcal{L}_{mf} , and the last equality is by Eckart–Young–Mirsky Theorem. So we know $\mathcal{L}_{\text{mf}}(f) \geq \left((1-\lambda_i)^2-(1-\lambda_{k+1})^2\right)\left\|\Pi_f^\perp v_i\right\|_2^2 + \mathcal{L}_{\text{mf}}(f_{\text{pop}}^*)$, which implies that $\left\|\Pi_f^\perp v_i\right\|_2^2 \leq \frac{\epsilon}{(1-\lambda_i)^2-(1-\lambda_{k+1})^2} \leq \frac{\epsilon}{(\lambda_{k+1}-\lambda_i)^2}$.

The following lemma generalizes Lemma B.6.

Lemma D.11 (Generalization of Lemma B.6). Let L be the normalized Laplacian matrix of graph $G = (\mathcal{X}, w)$, where $|\mathcal{X}| = N$. Let $f : \mathcal{X} \to \mathbb{R}^k$ be an ϵ -optimal minimizer of $\mathcal{L}_{mf}(f)$ where $\epsilon < (1 - \lambda_k)^2$. Let F be the matrix form of f and F_i is the i-th column of F. Let $R(u) := \frac{u^\top Lu}{u^\top u}$ be the Rayleigh quotient of a vector $u \in \mathbb{R}^N$. Then, for any $k \in \mathcal{Z}^+$ such that k < N, there exists a vector $b \in \mathbb{R}^k$ such that

$$\left\| u - \sum_{i=1}^{k} b_i F_i \right\|_2^2 \le \min_{1 \le k' \le k} \left(\frac{2R(u)}{\lambda_{k'+1}} + \frac{2k'\epsilon}{(\lambda_{k+1} - \lambda_{k'})^2} \right) \|u\|_2^2.$$

Proof. Let k' be the choice that minimizes the right hand side. We use $p_v(u)$ to denote the projection of u onto the span of $v_1, \dots, v_{k'}$. We use $p_{v,f}(u)$ to denote the projection of $p_v(u)$ onto the span of f_1, \dots, f_k . Then we know that

$$||u - p_{v,f}(u)||_2^2 \le 2 ||u - p_v(u)||_2^2 + 2 ||p_v(u) - p_{v,f}(u)||_2^2.$$
(30)

By the proof of Lemma B.6, we know that

$$\|u - p_v(u)\|_2^2 \le \frac{R(u)}{\lambda_{k'+1}} \|u\|_2^2.$$
 (31)

On the other hand, we have

$$||p_{v}(u) - p_{vf}(u)||_{2}^{2} = ||\Pi_{f}^{\perp} p_{v}(u)||_{2}^{2}$$

$$= ||\sum_{i=1}^{k'} \Pi_{f}^{\perp} v_{i} v_{i}^{\top} u||_{2}^{2}$$

$$\leq \left(\sum_{i=1}^{k'} ||\Pi_{f}^{\perp} v_{i}||_{2}^{2}\right) \cdot \left(\sum_{i=1}^{k'} (v_{i}^{\top} u)^{2}\right)$$

$$\leq \frac{k' \epsilon}{(\lambda_{k+1} - \lambda_{k'})^{2}} ||u||_{2}^{2}, \tag{32}$$

where the first inequality if by Cauchy–Schwarz inequality and the second inequality if by Lemma D.10. Plugging Equation (31) and Equation (32) into Equation (30) finishes the proof.

Now we prove Theorem D.8 using the above lemmas.

Proof of Theorem D.8. By Lemma D.9, the ϵ -optimal minimizer of $\mathcal{L}(f)$ is only different from ϵ -optimal minimizer of $\mathcal{L}_{mf}(f)$ by a positive constant for each x. Since this difference won't influence the perdiction accuracy, we only need to prove this theorem assuming \hat{f} is ϵ -optimal minimizer of $\mathcal{L}_{mf}(f)$.

For each $i \in [r]$, we define the function $u_i(x) = \mathbb{1} [\hat{y}(x) = i] \cdot \sqrt{w_x}$. Let $u : \mathcal{X} \to \mathbb{R}^k$ be the function such that u(x) has u_i at the i-th dimension. By Lemma D.11, there exists a vector $b_i \in \mathbb{R}^k$ such that

$$\left\| u_i - \widehat{F}b_i \right\|_2^2 \le \min_{1 \le k' \le k} \left(\frac{2R(u_i)}{\lambda_{k'+1}} + \frac{2k'\epsilon}{(\lambda_{k+1} - \lambda_{k'})^2} \right) \left\| u_i \right\|_2^2$$

Let matrices $U = [u_1, \dots, u_r]$ and $\widehat{B}^{\top} = [b_1, \dots, b_r]$. We sum the above equation over all $i \in [r]$ and get

$$\left\| U - \widehat{F}\widehat{B}^{\top} \right\|_{F}^{2} \leq \sum_{i=1}^{r} \min_{1 \leq k' \leq k} \left(\frac{2R(u_{i})}{\lambda_{k'+1}} + \frac{2k'\epsilon}{(\lambda_{k+1} - \lambda_{k'})^{2}} \right) \|u_{i}\|_{2}^{2}$$

$$\leq \min_{1 \leq k' \leq k} \sum_{i=1}^{r} \left(\frac{2R(u_{i})}{\lambda_{k'+1}} \|u_{i}\|_{2}^{2} + \frac{2k'\epsilon}{(\lambda_{k+1} - \lambda_{k'})^{2}} \|u_{i}\|_{2}^{2} \right). \tag{33}$$

Notice that

$$\sum_{i=1}^{r} R(u_{i}) \|u_{i}\|_{2}^{2} = \sum_{i=1}^{r} \frac{1}{2} \phi_{i}^{\hat{y}} \sum_{x \in \mathcal{X}} w_{x} \cdot \mathbb{1} \left[\hat{y}(x) = i \right]$$

$$= \frac{1}{2} \sum_{i=1}^{r} \sum_{x, x' \in \mathcal{X}} w_{xx'} \cdot \mathbb{1} \left[(\hat{y}(x) = i \wedge \hat{y}(x') \neq i) \text{ or } (\hat{y}(x) \neq i \wedge \hat{y}(x') = i) \right]$$

$$= \frac{1}{2} \sum_{x, x' \in \mathcal{X}} w_{xx'} \cdot \mathbb{1} \left[\hat{y}(x) \neq \hat{y}(x') \right] = \frac{1}{2} \phi^{\hat{y}}, \tag{34}$$

where the first equality is by Claim B.7. On the other hand, we have

$$\sum_{i=1}^{r} \|u_i\|_2^2 = \sum_{i=1}^{r} \sum_{x \in \mathcal{X}} w_x \cdot \mathbb{1} \left[\hat{y}(x) = i \right] = \sum_{x \in \mathcal{X}} w_x = 1.$$
 (35)

Plugging Equation (34) and Equation (35) into Equation (33) gives us

$$\left\| U - \widehat{F}\widehat{B}^{\top} \right\|_F^2 \le \min_{1 \le k' \le k} \left(\frac{\phi^{\widehat{y}}}{\lambda_{k'+1}} + \frac{2k'\epsilon}{(\lambda_{k+1} - \lambda_{k'})^2} \right).$$

Notice that by definition of u(x), we know that prediction $g_{\hat{f},\widehat{B}}(x) \neq \hat{y}(x)$ only happens if $\left\|u(x) - \widehat{B}\hat{f}(x)\right\|_2^2 \geq \frac{w_x}{2}$. Hence we have

$$\sum_{x \in \mathcal{X}} \frac{1}{2} w_x \cdot \mathbb{1} \left[g_{\hat{f}, \widehat{B}}(x) \neq \hat{y}(x) \right] \leq \sum_{x \in \mathcal{X}} \left\| u(x) - \widehat{B} \hat{f}(x) \right\|_2^2 = \left\| U - \widehat{F} \widehat{B}^\top \right\|_F^2.$$

Now we are ready to bound the error rate on \mathcal{X} :

$$\Pr_{x \sim \mathcal{X}}(g_{\hat{f},\widehat{B}}(x) \neq \hat{y}(x)) = \sum_{x \in \mathcal{X}} w_x \cdot \mathbb{1}\left[g_{\hat{f},\widehat{B}}(x) \neq \hat{y}(x)\right]$$

$$\leq 2 \cdot \left\|U - \hat{f}\widehat{B}^{\top}\right\|_F^2 \leq \min_{1 \leq k' \leq k} \left(\frac{2\phi^{\hat{y}}}{\lambda_{k'+1}} + \frac{4k'\epsilon}{(\lambda_{k+1} - \lambda_{k'})^2}\right).$$

Here for the equality we are using the fact that $Pr(x) = w_x$. We finish the proof by noticing that by the definition of $\Delta(y, \hat{y})$:

$$\begin{split} \Pr_{\bar{x} \sim \mathcal{P}_{\overline{\mathcal{X}}}, x \sim \mathcal{A}(\cdot | \bar{x})} \left(g_{\hat{f}, \widehat{B}}(x) \neq y(\bar{x}) \right) &\leq \Pr_{\bar{x} \sim \mathcal{P}_{\overline{\mathcal{X}}}, x \sim \mathcal{A}(\cdot | \bar{x})} \left(g_{\hat{f}, \widehat{B}}(x) \neq \hat{y}(x) \right) + \Pr_{\bar{x} \sim \mathcal{P}_{\overline{\mathcal{X}}}, x \sim \mathcal{A}(\cdot | \bar{x})} \left(y(\bar{x}) \neq \hat{y}(x) \right) \\ &\leq \min_{1 \leq k' \leq k} \left(\frac{2\phi^{\hat{y}}}{\lambda_{k'+1}} + \frac{4k'\epsilon}{(\lambda_{k+1} - \lambda_{k'})^2} \right) + \Delta(y, \hat{y}). \end{split}$$

E Proofs for Section 5

In this section we give the proof of Theorem 5.1. We first introduce the following lemma, which states the expected norm of representations:

Lemma E.1. Let $f_{pop}^*: \mathcal{X} \to \mathbb{R}^k$ be a minimizer of population spectral contrastive loss $\mathcal{L}(f)$. Then, we have

$$\mathbb{E}_{\bar{x} \sim \mathcal{P}_{\overline{\mathcal{X}}}, x \sim \mathcal{A}(\cdot | \bar{x})} \left[\left\| f_{\text{pop}}^*(x) \right\|_2^2 \right] \le k. \tag{36}$$

Proof of Lemma E.1. By Lemma B.8 and the definition of w, we have

$$\mathbb{E}_{\bar{x} \sim \mathcal{P}_{\overline{\mathcal{X}}}, x \sim \mathcal{A}(\cdot | \bar{x})} \left[\left\| f_{\mathsf{pop}}^*(x) \right\|_2^2 \right] = \sum_{x \in \mathcal{X}} w_x \left\| f_{\mathsf{pop}}^*(x) \right\|_2^2 = \sum_{x \in \mathcal{X}} \left\| \hat{f}_{\mathsf{ma}}(x) \right\|_2^2 = \left\| \hat{F}_{\mathsf{mf}} \right\|_F^2, \tag{37}$$

where \hat{F}_{mf} is a minimizer of the matrix approximation loss defined in Section 3.2. By Eckard-Young-Mirsky theorem, \hat{F}_{mf} looks like

$$\widehat{F}_{\rm mf} = F_{\rm sc} D_{\lambda} Q,$$

where $F_{\rm sc}=[v_1,v_2,\cdots,v_k]$ contains the k smallest eigenvectors of the laplacian matrix L as columns, Q is an orthonomal matrix and

$$D_{\lambda} = \begin{bmatrix} \sqrt{1 - \lambda_1} & & & \\ & \sqrt{1 - \lambda_2} & & \\ & & \cdots & \\ & & \sqrt{1 - \lambda_k} \end{bmatrix}.$$

So we have

$$\left\|\widehat{F}_{\mathrm{mf}}\right\|_{F}^{2} = Tr\left(F_{\mathrm{sc}}D_{\lambda}^{2}F_{\mathrm{sc}}^{\top}\right) \leq Tr\left(F_{\mathrm{sc}}F_{\mathrm{sc}}^{\top}\right) = k,$$

where we use the fact that D_{λ} has diagonal values less than 1 and v_i is unit-norm. Pluggin this into Equation (37) finishes the proof.

Now we give the proof of Theorem 5.1:

Proof of Theorem 5.1. Let f_{pop}^* be the minimizer of population spectral contrastive loss $\mathcal{L}(f)$. We abuse notation and use y_i to denote $y(\bar{x}_i)$, and let $z_i = f_{pop}^*(x_i)$. We first study the average empirical Rademacher complexity of the capped quadratic loss on a dataset $\{(z_i, y_i)\}_{i=1}^n$, where (z_i, y_i) is sampled as in Section 5:

$$\widehat{\mathcal{R}}_n(\ell) := \mathbb{E}_{\{(z_i, y_i)\}_{i=1}^n} \mathbb{E}_{\sigma} \left[\sup_{\|B\|_F \le 1/C_{\lambda}} \frac{1}{n} \left[\sum_{i=1}^n \sigma_i \ell((z_i, y_i), B) \right] \right]$$

$$\leq 2r \mathbb{E}_{\{(z_i, y_i)\}_{i=1}^n} \mathbb{E}_{\sigma} \left[\sup_{\|b\|_2 \le 1/C_{\lambda}} \frac{1}{n} \left[\sum_{i=1}^n \sigma_i w^{\top} z_i \right] \right]$$

$$\leq \frac{2r}{C_{\lambda}} \sqrt{\frac{\mathbb{E}[\|z_i\|^2]}{n}} \leq \frac{2r\sqrt{k}}{C_{\lambda}\sqrt{n}},$$

where the first inequality uses Talagrand's lemma and the fact that ℓ_{σ} is 2-Lipschitz, the second inequality is by standard Rademacher complexity of linear models, the third inequality is by Lemma E.1.

By Theorem B.2, there exists a linear probe B^* with norm bound $\|B^*\|_F \le 1/(1-\lambda_k) \le 1/C_\lambda$ such that

$$\mathbb{E}_{\bar{x} \sim \mathcal{P}_{\overline{\mathcal{X}}}, x \sim \mathcal{A}(\cdot | \bar{x})} \left[\ell \left((f_{\mathsf{pop}}^*(x), y(\bar{x})), B^* \right) \right] \lesssim \mathsf{poly}(1/\zeta) \log(k+1) \cdot \frac{\phi^{\hat{y}}}{\rho_{t_{\ell}}^2} + \Delta(y, \hat{y}),$$

where $(1+\zeta)k'=k+1$. Let \widehat{B} be the minimizer of $\sum_{i=1}^n \ell\left((z_i,y_i),B\right)$ subject to $\|B\|_F \leq 1/C_{\lambda}$, then by standard generalization bound, we have: with probability at least $1-\delta$, we have

$$\mathbb{E}_{\bar{x} \sim \mathcal{P}_{\overline{\mathcal{X}}}, x \sim \mathcal{A}(\cdot | \bar{x})} \left[\ell \left((f_{\mathsf{pop}}^*(x), y(\bar{x})), \widehat{B} \right) \right] \lesssim \mathsf{poly}(1/\zeta) \log(k+1) \cdot \frac{\phi^{\hat{y}}}{\rho_{k'}^2} + \Delta(y, \hat{y}) + \frac{r\sqrt{k}}{C_\lambda \sqrt{n}} + \sqrt{\frac{\log 1/\delta}{n}}.$$

Follow the same steps as in the proof of Theorem 3.7, we can get a genalization bound of

$$\mathbb{E}_{\bar{x} \sim \mathcal{P}_{\overline{x}}, x \sim \mathcal{A}(\cdot | \bar{x})} \left[\ell \left((f^*_{\mathsf{pop}}(x), y(\bar{x})), \widehat{B} \right) \right] \lesssim \frac{\alpha}{\rho_{|k/2|}^2} \cdot \log k + \frac{r}{C_{\lambda}} \cdot \sqrt{\frac{k}{n}} + \sqrt{\frac{\log 1/\delta}{n}}.$$

Notice that $y(\bar{x}) \neq g_{f^*_{\mathrm{pop}},\widehat{B}}(x)$ only if $\ell\left((f^*_{\mathrm{pop}}(x),y(\bar{x})),\widehat{B}\right) \geq \frac{1}{2}$, we have the error bound

$$\Pr_{\bar{x} \sim \mathcal{P}_{\overline{\mathcal{X}}}, x \sim \mathcal{A}(\cdot | \bar{x})} \left(g_{f^*_{\mathsf{pop}}, \widehat{B}}(x) \neq y(\bar{x}) \right) \lesssim \frac{\alpha}{\rho^2_{\lfloor k/2 \rfloor}} \cdot \log k + \frac{r}{C_{\lambda}} \cdot \sqrt{\frac{k}{n}} + \sqrt{\frac{\log 1/\delta}{n}}.$$

The result on $\bar{g}_{f^*_{\text{DDD}},\widehat{B}}$ naturally follows by the definition of \bar{g} .

F Formal statements for population with infinite supports

In the main body of the paper, we make the simplifying assumption that the set of augmented data $\mathcal X$ is finite (but could be exponential in dimension). Although this is a reasonable assumption given that modern computers store data with finite bits so the possible number of all data has to be finite, one might wonder whether our theory can be generalized to the case where $\mathcal X$ is infinite (e.g., the entire Euclidean space $\mathbb R^d$ for some integer d>0). In this section, we show that our theory can be straightforwardly extended to the case when $\mathcal X$ has infinite supports with some additional regularity conditions. In fact, almost all proofs remain the same as long as we replace sum by integral, finite graph by an infinite graph, adjacency matrix by adjacency operator, and eigenvectors by the eigenfunctions.

For simplicity, we consider the case when $\mathcal{X}=\mathbb{R}^d$ is the set of all augmented data.⁷ The weight matrix $w_{xx'}$ now becomes a weight function $w:\mathcal{X}\times\mathcal{X}\to\mathbb{R}$. As usual, let w(x,x') be the marginal probability of generating the pair x and x' from a random natural datapoint $\bar{x}\sim\mathcal{P}_{\overline{\mathcal{X}}}$. Or in other words, w is the p.d.f. of the joint distribution of a random positive pair. For any $u\in\mathcal{X}$, define the marginal weight function $w(u)\triangleq\int w(u,z)dz$. A sufficient (but not necessary) condition for our theory to hold is as follows:

Assumption F.1 (Regularity conditions). *The distribution w satisfies the following conditions:*

- (i) For any $u \in \mathcal{X}$, the marginal distribution is well-defined and bouned $w(u) = \int w(u, z) dz < \infty$.
- (ii) There exists B>0 such that for every $u,v\in\mathcal{X}$, the conditional probability with respect to one variable is upper bounded by the marginal probability of the other variable $\frac{w(u,v)}{w(u)}\leq B\cdot w(v)$.

We note that our bound does not depend on value of B—we only the existence of B for a qualitative purpose. When the regularity conditions above hold, we will show that there exists an eigenfunction of the infinite adjacency graph is an analog to the eigenvectors of Laplacian that we introduced in Section B.

Let $L_2(\mathbb{R}^d)$ be the set of all L_2 integratable functions $L_2(\mathbb{R}^d) \triangleq \{f : \mathbb{R}^d \to \mathbb{R} \mid \int f(z)^2 dz < \infty\}$. For functions $f, g \in L_2(\mathbb{R}^d)$, define their inner product as $\langle f, g \rangle \triangleq \int f(z)g(z)dz$. Note that $\ell_2(\mathbb{R}^d)$ is a Hilbert space.

To generalize the Laplacian matrix and eigenvectors to the infinite-size $\mathcal X$ setting, we consider the notions of Laplacian operators and eigenfunctions. Let $H:L_2(\mathbb R^d)\to L_2(\mathbb R^d)$ be a linear operator, a function $f\in L_2(\mathbb R^d)$ is an eigenfunction of H if $H(f)(u)=\lambda f(u)$ for any $u\in \mathcal X$, where $\lambda\in\mathbb R$ is the corresponding eigenvalue. We define the Laplacian operator as $L:L_2(\mathbb R^d)\to L_2(\mathbb R^d)$ such that for every $u\in \mathcal X$ and function $f\in L_2(\mathbb R^d)$, we have

$$L(f)(u) = f(u) - \int \frac{w(u,v)}{\sqrt{w(u)w(v)}} f(v)dv.$$
(38)

The following theorem shows the existence of eigenfunctions of the Laplacian operator.

Theorem F.2 (Existence of Eigenfunctions). When Assumption F.1 is satisfied, there exists an orthonormal basis $\{f_i\}_{i=1}^{\infty}$ of $L_2(\mathbb{R}^d)$ such that $L(f_i) = \lambda_i f_i$. Furthermore, the eigenvalues satisfy $\lambda_i \in [0,1]$ and $\lambda_i \leq \lambda_{i+1}$ for any $i \geq 0$.

⁷When \mathcal{X} is a subset of \mathbb{R}^d equipped with a base measure μ , then we will need to replace every dx by $d\mu$ in the formulation below.

Proof of Theorem F.2. Define kernel function $k(u,v) \triangleq \frac{w(u,v)}{\sqrt{w(u)w(v)}}$, we have

$$\int k(u,v)^2 du dv = \int \frac{w(u,v)^2}{w(u)w(v)} du dv \le B \int w(u,v) du dv = B < \infty.$$
(39)

Let I be the identity operator, then L-I is a Hilbert–Schmidt integral operator (Wikipedia contributors, 2020), so the spectral theorem (Bump, 1998) applies to L-I hence also applies to L. By the spectral theorem, there exists an orthonormal basis $\{f_i\}_{i=1}^{\infty}$ of $L_2(\mathbb{R}^d)$ such that $L(f_i) = \lambda_i f_i$.

Notice that

$$\lambda_i = \langle f_i, L(f_i) \rangle = \langle f_i, f_i \rangle - \int \frac{w(u, v)}{\sqrt{w(u)w(v)}} f_i(u) f_i(v) du dv.$$
 (40)

On the one hand, since $w(u, v) \ge 0$ and $\langle f_i, f_i \rangle = 1$, we have $\lambda_i \le 1$. On the other hand, notice that by Cauchy-Schwart inequality,

$$\int \frac{w(u,v)}{\sqrt{w(u)w(v)}} f_i(u) f_i(v) du dv \le \sqrt{\int f_i(u)^2 \frac{w(u,v)}{w(u)} du dv} \cdot \int f_i(v)^2 \frac{w(u,v)}{w(v)} du dv = \langle f_i, f_i \rangle, \tag{41}$$

so $\lambda_i \geq 0$, which finishes the proof.

Given the existence of eigenfunctions guaranteed by Theorem F.2, our results Theorem 3.7, Theorem 4.2 and Theorem 5.1 can all be easily generalized to the infinite-size \mathcal{X} case following exactly the same proof. For example, in the context of Lemma 3.2, u_x will be replaced by u(x): $\mathbb{R}^d \to \mathbb{R}$ which belongs to $L_2(\mathbb{R}^d)$, and $f(x) = w(x)^{1/2}u(x)$ as a result belongs to $L_2(w)$. Let $\mathcal{L}_{\mathrm{mf}}(f) = \langle u, Lu \rangle_{L_2(\mathbb{R}^d)} = \langle f, Lf \rangle_{L_2(w)}$. The rest of the derivations follows by replacing the sum in equation (7) by integral (w.r.t to Lebesgue measure). More details on the normalized Laplacian operator and spectral clustering can be found in (Schiebinger et al., 2015).

We omit the proof for simplicity.
